(Received 10 February 2011; accepted 12 April 2011; published online 3 May 2011)

We present a method for decoupling epitaxial graphene grown on SiC(0001) by intercalation of a layer of fluorine at the interface. The fluorine atoms do not enter into a covalent bond with graphene but rather saturate the substrate Si bonds. This configuration of the fluorine atoms induces a remarkably large hole density of \( p \approx 4.5 \times 10^{13} \ \text{cm}^{-2} \), equivalent to the location of the Fermi level at 0.79 eV above the Dirac point \( E_D \). © 2011 American Institute of Physics.

Many applications of graphene, the single layer of hexagonally coordinated carbon atoms have been proposed since the discovery of its unusual electronic properties.1 For these applications to be realized, the ability to achieve n- and p-type doping is required. While n-type doping is observed in graphene grown epitaxially on SiC,2,3 only marginal p-type doping has been achieved by hydrogen4–7 and Au5–7-doping of the graphene is observed, while Au6-doping is required. While n-doping of the graphene is observed, -type doping has been achieved by hydrogen4–7 and Au5–7, respectively. Surface treatment with 1013 cm−2, equivalent to the location of the Fermi level surface, where the theoretical10 and experimental11–14 band network so that the \((6\sqrt{3} \times 6\sqrt{3})R30^\circ\) layer (henceforth buffer layer) has no Dirac cone. Hydrogen and gold have been shown to intercalate underneath the buffer layer, breaking the carbon bonds to the substrate and thus decoupling it from the SiC and transforming it into graphene.4–7 Samples were fluorinated following a similar method to McFeely et al.18 whereby buffer layer samples are placed in a reaction chamber with a XeF2 crystal and heated to 200 °C for 2 h, leading to the dissociation of the XeF2 and the liberation of reactive fluorine atoms. This method has previously been used to study the interaction between fluorine and silicon surfaces18 as well as fluorine and graphene11–14 and normally leads to the formation of C–F bonds with the graphene layer. If a sacrificial piece of molybdenum is included in the reaction chamber, an entirely different reaction is promoted, whereby the F atoms bond not to the buffer layer C atoms, but instead to the interfacial Si atoms, as discussed below. At high pressure, XeF2 reacts with the molybdenum to produce MoF6 through the well-known reactions (depending on whether the Mo is clean or oxidized),19,20

\[
3\text{XeF}_2 + \text{Mo} \rightarrow \text{MoF}_6(g) + 3\text{Xe}(g),
\]

\[
6\text{XeF}_2 + 2\text{MoO}_3 \rightarrow 2\text{MoF}_6(g) + 6\text{Xe}(g) + 3\text{O}_2(g).
\]

Following the fluorination process, the samples are covered by a layer of Mo (oxidized by air exposure), which is readily removed by sonication in ethanol. The presence of this Mo residue indicates that it is the gaseous MoF6, not XeF2, that interacts with the graphene. Samples were transported through air to the electronic structure factory endstation at beamline 7 of the Advanced Light Source, Lawrence Berkeley National Laboratory and annealed to ∼600 °C in vacuum to clean the surface for ARPES and core level measurements.

The Fermi surfaces and band structures of three samples are presented in Figs. 1(a) and 1(d), a buffer-layer sample (6√3 × 6√3)R30°/SiC without fluorination; Figs. 1(b) and 1(e), the same buffer-layer sample later treated with fluorine; and for comparison, Figs. 1(c) and 1(f), a graphene sample grown conventionally, consisting of an active graphene layer on top of the inactive buffer layer.17

As reported previously, the buffer layer sample is insulating,17 having no Fermi surface and having only a flat band appearing around 0.4 eV binding energy [see Figs. 1(a) and 1(d)]. After fluorination, the circular Fermi surface and linear bands of graphene appear. Projection of the linear bands indicate a Dirac crossing well above the Fermi level, as expected for p-type doping, and extrapolating the band to the region above the Fermi edge locates it 0.79 eV above $E_F$. The Fermi surface size can be used21 to quantitatively evaluate the hole density at $(p=4.5×10^{13}$ cm$^{-2}$), which is an order of magnitude larger than previously observed for H intercalated graphene $(p=6×10^{12}$ cm$^{-2}$). For comparison, the conventional Argon grown graphene buffer on SiC samples16 are n-type with a much smaller charge density $(n=1×10^{13}$ cm$^{-2}$) and Fermi surface [Figs. 1(c) and 1(f)]. These results suggest that the buffer layer is transformed by fluorination into a p-type graphene. The linewidth of the ARPES $\pi$ bands at the Fermi level ($\sim 0.014$ Å$^{-1}$), which directly gives the electron mean-free path from defect scattering, is comparable to that from the conventional graphene sample ($\sim 0.009$ Å$^{-1}$) indicating a similar clean, defect-free graphene layer on the fluorine samples. We now discuss core-level photoemission measurements of samples (i) and (ii) which demonstrate that the fluorine intercalates under the buffer-layer/SiC interface. This is completely different from fluorographene/fluorographene materials recently discovered, which are wide band gap semiconductors owing to covalent C–F bond formation.18,19,22

Core level photoemission spectra of the buffer layer before and after exposure to fluorine are presented in Fig. 2. After fluorine treatment, a clear F 1s peak is observed at 686.9 eV binding energy (not shown), confirming the presence of fluorine. Except for a small residual oxygen peak only peaks relating to C, F, and Si are present in XPS scans up to a binding energy of 850 eV. The Si 2p peak features [Fig. 2(a)] are comparable to previous data from the buffer layer24 and are fitted to two doublets representing the bulk (SiC) and surface (S) contributions (Ref. 23). Fluorine bonding to interfacial Si is indicated by a shift in the surface doublet, S, of $-0.18$ eV after fluorination. (b) C 1s core levels before fluorination consist of a bulk (SiC) peak and two surface peaks $(S_1$, $S_2$) representing buffer layer C atoms bonded to the substrate (Ref. 17). After fluorination, the latter peaks are weakened, and a new graphene-derived peak (G) is observed. No C–F bonds are observed.
top spectrum is from the buffer layer before fluorination and exhibits two peaks ($S_1, S_2$), which arise from the bonding of the carbon atoms in the buffer layer to the SiC substrate, at $\sim-285.55$ and $-284.75$ eV, and a peak at $\sim-283.7$ eV due to the bulk SiC. Upon exposure to fluorine, buffer layer peaks $S_1, S_2$ are largely suppressed, and a new peak ($G$) at $\sim-284.05$ eV appears, attributed to the formation of the graphene layer. Its separation to the carbon peak from the SiC bulk is much smaller than for graphene on buffer/SiC samples ($\sim-284.74$ eV), which is related to the fact that the graphene is strongly doped. The C 1s spectrum in Fig. 2(b) (lower) also shows none of the C–F peaks of perfluorographene [12] or any peaks in the range 285 to 290 eV expected for C–F bonding, [12,25] for that matter. This provides strong evidence that the fluorine does not bond covalently to the graphene layer. The buffer layer peaks are still present after fluorination, indicating that only partial fluorination of the sample has occurred. Thus the buffer layer is transformed into a single layer of graphene by intercalation, similar to the effect of hydrogen observed in quasifreestanding samples. [4,5]

In summary, using core and valence band photoemission we demonstrate that fluorine interacts with monolayers and bilayers of graphene on buffer layer/SiC, to produce highly $p$-doped bilayer and trilayer graphene, respectively, by converting their buried buffer layers to graphene. Although a detailed interpretation of the binding energy shifts reported above is difficult without considering local field effects, a qualitative picture emerges of an interfacial fluorine layer, chemically bound to Si atoms, which is fully ionic owing to charge transfer from both the Si and from the graphene C atoms. Comparison of the peak areas of the F 1s and the C 1s graphene peak [peak $G$ in Fig. 2(b)], and applying the correct photoemission cross-section ratio, [26] gives (Graphene C)/F atomic ratio of $\sim4.6$. As we have shown that the F bonds to the surface Si not the graphene C then the important ratio is $S_{\text{surface}}$/F atomic ratio ($\sim1.7$), implying a 60% fluorination of the sample.

In summary, using core and valence band photoemission we demonstrate that fluorine interaction with the carbon buffer layer on SiC leads to the formation of a strongly $p$-doped graphene layer that is decoupled from the substrate through intercalation, shifting the Dirac crossing point to 0.79 eV above the Fermi energy. This is the strongest $p$-type doping ever observed in graphene, and the fact that the intercalated structure is stable against ambient conditions suggests its use in applications. Moreover, the doping process may be patterned, which could lead to laterally structured $n-p-n$ devices.

The Advanced Light Source is supported by the Director, Office of Science, Office of Basic Energy Sciences, of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231. Work in Erlangen was supported by the ESF and the DFG through the EUROCORES program EU-ROGRAPHENE.
