(Received 23 February 2005; published 22 July 2005)

We present a mathematical framework for simulation of optical fields in complex gravitational-wave interferometers. The simulation framework uses the two-photon formalism for optical fields and includes radiation pressure effects, an important addition required for simulating signal and noise fields in next-generation interferometers with high circulating power. We present a comparison of results from the simulation with analytical calculation and show that accurate agreement is achieved.

I. INTRODUCTION

Next-generation gravitational-wave (GW) interferometers, such as those planned for Advanced LIGO (Laser Interferometer Gravitational-wave Observatory) [1], are designed to have a 15-fold improvement in sensitivity over present-day detectors [2]. Among the techniques planned to achieve this improved sensitivity is an increase in the input laser power. The higher laser power reduces the shot noise limit at frequencies above ~100 Hz, as intended, but has the deleterious effect of increasing the radiation-pressure noise at lower frequencies. Consequently, advanced detector sensitivity at almost all frequencies in the detection band is expected to be limited by quantum noise. Qualitatively speaking, shot noise and radiation-pressure noise correspond to measurement noise and back action noise in quantum measurement theory—together they often impose the standard quantum limit (SQL) to measurement accuracy [3]. A correct modeling of the quantum noise of a GW interferometer should take into account correlations between the two types of noises, which may allow sub-SQL sensitivities to be achieved [3–5].

The need for optical field simulation for gravitational-wave interferometer design has been addressed in the past with a variety of simulation tools, both in the frequency domain (e.g., twiddle [6] and finesse [7]) and in the time domain (e.g., the LIGO end-to-end simulation program [8]). Although time-domain simulations can study issues associated with large mirror displacements and nonlinear effects, e.g., the lock acquisition of the interferometer, they are computationally costly; in addition, full time-domain simulations are also less straightforward to quantize. In order to study the performance of gravitational-wave detectors, it suffices to stay in the linear regime near the operation point. For such a linear problem, frequency-domain simulations are dramatically simpler than time-domain ones; it is straightforward to obtain frequency-domain transfer functions, and therefore noise spectra. In addition, since the system is linear, the propagation of quantum Heisenberg operators are identical to those of classical field amplitudes, therefore it suffices to build an essentially classical propagator.

In low-power situations where radiation-pressure-induced mirror motion is negligible and no nonlinear optical elements (e.g., squeezers) are used, when linearizing over mirror displacements, propagation of electromagnetic fields at different frequencies are independent, and therefore the transfer functions can be established for each different frequency separately. One only needs to take into account that, for the inputs to this linear system: (i) mirror motion (with frequency Ω) creates phase modulation of the carrier, which is equivalent to generating two equally spaced sidebands on the carrier frequency (at ω±Ω, where ω is the carrier frequency and we denote ω+Ω and ω−Ω as the upper and lower sidebands, respectively) with opposite amplitudes, and that (ii) laser noise can usually be decomposed into amplitude noise and phase noise, with the former contributing equally to the upper and lower sidebands, and the latter oppositely. These considerations have been the conceptual foundations of previous frequency-domain simulation programs.

For high-power interferometers, the above strategy will have to be modified: The radiation-pressure forces acting on the mirrors, at frequency Ω, depend on both upper and lower sideband fields; the induced mirror motion will again contribute to both sidebands—this makes it necessary to propagate pairs of upper and lower sidebands simultaneously. The mathematical formalism most convenient for this problem, at least in the case of only one carrier frequency, is the Caves-Schumaker two-photon formalism [9,10]. In this paper, we adopt this formalism and present a mathematical framework for calculating the propagation of fields in an arbitrary optical system that includes the dynamical response of the mirrors to the light field. Namely, we divide complex interferometers into interconnected elementary subsystems, and provide a general procedure for building a set of linear equations for all optical fields propagating between these systems—based on each individual system’s input-output relation, i.e., transformation matrices relating output fields to input ones and the incoming GW. We also describe the way in which these subsystems are connected to each other. Solving these equations will provide us with the optical fields, in terms of vacuum fluctuations entering the system from open ports, laser noise, and incoming GWs. While this mathema-
cal framework, and the resulting numerical simulation tool, were developed to model quantum correlation effects in gravitational-wave interferometers, the method is general and can be used in any system where optical fields couple to mechanical oscillation modes.

The paper is organized as follows: In Sec. II we introduce the mathematical framework for the simulation, and illustrate it with a simple example; in Sec. III we provide input-output relations of basic optical elements that may be present in a laser interferometer, ignoring radiation-pressure effects and the presence of gravitational waves—by reformattting well-known results in optics; in Sec. IV, we take radiation-pressure-induced mirror motion into account, and provide input-output relations for movable mirrors and beamsplitters (up to linear order in mirror motion), which have not been obtained before in the most general form; in Sec. V, we take into account the presence of GWs by introducing modulation of cavity lengths, and treat the corresponding effect on light propagation up to linear order in $L/L_{GW}$ (with $L$ the length of the interferometer). In Sec. VI the formulation is applied to an interferometer designed to extract squeezed vacuum states that are created by a strong optomechanical coupling; and, finally, conclusions are summarized in Sec. VII.

II. MATHEMATICAL FRAMEWORK

A. General prescription

As mentioned above, the presence of optomechanical coupling dictates that we propagate the upper and lower sidebands simultaneously, which means that for each frequency $\Omega$, we will have to work with the two-dimensional linear space spanned by the upper $[a(\omega+\Omega)]$ and lower $[a(\omega-\Omega)]$ sidebands. Within the two-photon formalism, developed by Schumaker and Caves [9,10], and outlined in the Appendix below, instead of $a(\omega\pm\Omega)$, the two quadrature fields $a_{1,2}(\Omega)$ are chosen as the basis vectors. For simplicity of notation, we generally denote

$$a = \begin{pmatrix} a_1 \\ a_2 \end{pmatrix}$$

and suppress the dependence of $a$ on $\Omega$.

We consider optomechanical systems formed by the following elementary subsystems: movable mirrors, beamsplitters, and free space propagators. We will also include a “linear squeezer,” which turns an ordinary vacuum state into a two-mode squeezed field with arbitrary squeeze factor and squeeze angle. Auxiliary to these optical elements, we introduce the beam block and the photodetector to deal with open ports which are either left undetected or detected with unit quantum efficiency; we also introduce the laser as an optical element, which injects monochromatic carrier light and laser noise into the interferometer. Quadrature optical fields undergo linear transformations when propagating through such elementary systems, and quadrature fields with different $\Omega$’s propagate independently from each other. These linear transformations are described mathematically by the input-output relation, namely, a set of equations relating the output fields to the input ones, including vacuum fluctuations, the carrier laser and laser fields, as well as to incoming GWs. We provide these input-output relations in Secs. III–V.

However, we note that propagation of sideband quadratures ($\Omega \neq 0$), although independent from each other, all depend on the propagation of the carrier quadratures ($\Omega = 0$), i.e., the amplitude and phase of the carrier incident on each subsystem. Fortunately, the propagation of the carrier is not affected by that of the sidebands, and can be carried out independently at the beginning. This said, we begin to formulate our general method of simulation.

We build the following system of linear equations (for each sideband frequency $\Omega$):

$$[\mathcal{M}_{11} \cdots \mathcal{M}_{1N} \cdots \mathcal{M}_{N1} \cdots \mathcal{M}_{NN}] [\begin{pmatrix} a^{(i)}_1 \\ \vdots \\ a^{(i)}_N \end{pmatrix}] = [\begin{pmatrix} u^{(i)}_1 \\ \vdots \\ u^{(i)}_N \end{pmatrix}],$$

where $a^{(i)}_i, i=1,\ldots,N$ are the $N$ quadrature fields (each of them a two-dimensional vector) propagating in every part of the system, $u^{(i)}_i, i=1,\ldots,N$ are $N$ generalized input quadrature fields (each of them again a two-dimensional vector). The $\mathcal{M}_{ij}, i,j=1,\ldots,N$ are $2\times2$ matrices which depend on the details of the optical system, and the $u^{(i)}_i$ can be written schematically as

$$u^{(i)} = \mathbf{v}^{(i)} + \mathbf{I}^{(i)} + \mathbf{H}^{(i)}h,$$

where $\mathbf{v}^{(i)}$ arises from vacuum fluctuations entering from the detection port or other lossy ports (Secs. II B, III, and IV), $\mathbf{I}^{(i)}$ from the laser (Sec. II B), and $\mathbf{H}^{(i)}h$ from GW-induced phase modulation, with $h$ the GW amplitude (Sec. V); depending on the location of this generalized input field, some or all of the above three contributions could also be zero. Henceforth in the paper, we shall consider each pair of quadrature fields as one object. Inverting the matrix $\mathcal{M}_{ij}$ will give $a^{(i)}$ in terms of $u^{(i)}$, and hence all of the necessary transfer functions.

Now let us provide a universal prescription for constructing Eq. (2), suitable for modeling generic systems. We break this procedure into two steps:

1. Suppose we have $n$ elementary subsystems mentioned above, with the $k$th subsystem having $p_k$ ports. The entire system will then have $P = \sum_{k=1}^n p_k$ ports. Because we formally include beam blocks and photodetectors as subsystems, none of our ports will be formally open, i.e., left unconnected to some other port. This means that we have $P/2$ pairs of connections. For each pair of connections, we have two fields, one propagating in each direction. This means we have a total of $P$ fields with two quadrature components each.

2. For each system $k$, with $p_k$ ports, we also have $p_k$ input fields and $p_k$ output fields, and therefore the input-output relation will provide us $p_k$ equations. All subsystems together will then provide us with $P$ equations, exactly the number needed.
B. Example with the input-output relation of beam blocks, photodetectors, and lasers

Next we illustrate the generic construction procedure with a simple example, which also clarifies the formal roles of beam blocks, photodetectors, and lasers. We first propagate fields through three basic elements of an optical train: a beam block, a partially reflecting mirror, and a photodetector. Referring to Fig. 1, the beam block is connected to the mirror, which is in turn connected to a detector. For simplicity, we assume that the mirror is lossless and fixed in position.

As a first step, we identify the fields in consideration. The beam block is a two-port system; we have a total of four ports, and 4/2 = 2 connections. There are two fields associated with each connection; we label them a, b, and c, d, respectively, as done in Fig. 1. Since each field has two quadrature components, the system is eight dimensional, and we need eight scalar equations.

Now we have to provide the input-output relations for each object. For the mirror with amplitude reflectivity ρ and transmissivity τ, and neglecting radiation pressure effects, we have

\[
\begin{pmatrix}
  b \\
  c \\
\end{pmatrix} =
\begin{pmatrix}
  -\rho & \tau \\
  \tau & -\rho \\
\end{pmatrix}
\begin{pmatrix}
  a \\
  d \\
\end{pmatrix} = \mathcal{M}_{\text{Mir}}
\begin{pmatrix}
  a \\
  d \\
\end{pmatrix}.
\]

(4)

Note that Eq. (4) contains four scalar equations, and that ρ and τ are really 2 × 2 scalar matrices, ρI, and τI (this is true because our mirror does not mix quadratures)—we have suppressed the identity matrix I for simplicity. To comply with the format of Eq. (2), we write

\[
\begin{pmatrix}
  -\rho & -1 & 0 & \tau \\
  \tau & 0 & -1 & \rho \\
\end{pmatrix}
\begin{pmatrix}
  a \\
  b \\
  c \\
  d \\
\end{pmatrix} = \begin{pmatrix}
  0 \\
  0 \\
\end{pmatrix}.
\]

(5)

For the beam block and the photodetector, they really are placeholders for physically open ports. Their input-output relation is simply that the output fields from them are vacuum fluctuations (independent from the input fields):

\[
a = v^{(1)}, \quad d = v^{(2)},
\]

(6)

Here we assume implicitly that the photodetector is detecting the field c with unit quantum efficiency. In order to model imperfect photodetectors, we could add a mirror with zero reflectivity and nonzero loss in front of the ideal photodetector.

Combining Eqs. (5) and (6), we have

\[
\begin{pmatrix}
  -1 & 0 & 0 & 0 \\
  -\rho & -1 & 0 & \tau \\
  \tau & 0 & -1 & \rho \\
  0 & 0 & 0 & -1 \\
\end{pmatrix}
\begin{pmatrix}
  a \\
  b \\
  c \\
  d \\
\end{pmatrix} =
\begin{pmatrix}
  -v^{(1)} \\
  0 \\
  0 \\
  -v^{(2)} \\
\end{pmatrix},
\]

(7)

which are the eight scalar equations we need. Inverting \(\mathcal{M}\) will give us each of the propagating fields in terms of the input vacuum fields.

Now suppose the beam block is replaced by a laser source, coupled to the spatial mode of a field, then we only need to replace the vacuum field \(v^{(1)}\) in Eqs. (6) and (7) by the laser field, \(l^{(1)}\); at \(\Omega = 0\), carrier quadratures, while at \(\Omega \neq 0\), it gives the laser noises.

Here we note that all diagonal elements of \(\mathcal{M}\) are equal to −1—this is in fact not a coincidence, but a universal feature of our construction procedure. In order to understand this, we need to realize that every field \(a^{(k)}\) is the output field of exactly one subsystem. In the input-output relation of that unique subsystem, there is exactly one line that relates \(a^{(k)}\) to the input fields of this subsystem, which reads

\[
a^{(k)} = [\text{terms not involving } a^{(k)}].
\]

(8)

This equation corresponds to, after moving \(a^{(k)}\) to the right-hand side of the equation, moving any non-\(a^{(j)}\), \(j = 1, \ldots, N\) terms to the left-hand side, and swapping left and right

\[
\begin{pmatrix}
  \cdots & -1 & \cdots \\
  \vdots & \vdots & \vdots \\
  a^{(1)} & \cdots & \cdots \\
  \vdots & \vdots & \vdots \\
  a^{(k)} & \cdots & \cdots \\
  \vdots & \vdots & \vdots \\
  a^{(N)} & \cdots & \cdots \\
\end{pmatrix} = \cdots.
\]

(9)

It is obvious that the lines of equation found by this way for different \(a^{(k)}\)'s will be different. As a consequence, we can arrange to have the line corresponding to \(a^{(k)}\) appear on the \(k\)th row of \(\mathcal{M}\), and thus have all its diagonal elements equal to −1.

III. MATRICES FOR STATIC OPTICAL ELEMENTS

In this section, we derive the matrices for some standard objects used in simulating quantum noise in a gravitational-wave interferometer. Here we neglect radiation pressure effects and the presence of gravitational waves (they will be dealt with in Secs. IV and V, respectively). As a consequence, our derivation only involves some reformattting of previously well-known results.

A. Mirrors

Field transformations due to a mirror were introduced in the example of Sec. II. The transformation matrix for a lossless mirror is given in Eq. (4). We now derive more complete equations for the mirror that include losses. We ascribe a power loss \(A\) to the mirror in Fig. 1 such that \(\rho^2 + \tau^2 + A = 1\). The introduction of losses gives rise to an additional vacuum
The new equations governing the mirror are
\[
\rho \left( a + \sqrt{\frac{A}{1-A}} v^{(3)} \right) + \tau \left( d + \sqrt{\frac{A}{1-A}} v^{(4)} \right)
\]
and
\[
\rho' \left( 1 + \frac{A}{1-A} \right) + \tau' \left( 1 + \frac{A}{1-A} \right) = \frac{1-A}{1-A} = 1.
\]
The new equations governing the mirror are
\[
\begin{pmatrix} b \\ c \end{pmatrix} = \begin{pmatrix} -\rho & \tau \\ \tau & \rho \end{pmatrix} \begin{pmatrix} a \\ d \end{pmatrix} + \sqrt{\frac{A}{1-A}} \begin{pmatrix} v^{(3)} \\ v^{(4)} \end{pmatrix}
\]
where \( v^{(3)} \) and \( v^{(4)} \) are the vacuum fluctuations that enter due to the presence of loss.

Equation (12) may be rewritten as
\[
\begin{pmatrix} b \\ c \end{pmatrix} = \begin{pmatrix} -\rho & \tau \\ \tau & \rho \end{pmatrix} \begin{pmatrix} a \\ d \end{pmatrix} + \sqrt{\frac{A}{1-A}} \begin{pmatrix} v^{(3)'} \\ v^{(4)'} \end{pmatrix},
\]
where
\[
v^{(3)'} = \sqrt{\frac{1}{1-A}} (-\rho v^{(3)} + \tau v^{(4)})
\]
and
\[
v^{(4)'} = \sqrt{\frac{1}{1-A}} (\tau v^{(3)} + \rho v^{(4)}).
\]
These methods may also be used to inject losses in beamsplitters or cavities.

B. Free space propagation

Since optical cavities are present in virtually all optical configurations of gravitational-wave interferometers, we must also be at the shot-noise level, such that
\[
-\rho \left( a + \sqrt{\frac{A}{1-A}} v^{(3)} \right) + \tau \left( d + \sqrt{\frac{A}{1-A}} v^{(4)} \right)
\]
must give a transformation matrix for them as an element of our arbitrary optical train. To do so we introduce an operator to transform the field as it propagates through free space between any two other optical elements (in the case of an optical cavity, these would be mirrors). Using the convention of Fig. 2, the matrix for propagation through a length \( L \) transforms input fields \( a \) and \( d \) according to
\[
\begin{pmatrix} b \\ c \end{pmatrix} = M_{\text{Prop}} \begin{pmatrix} a \\ d \end{pmatrix},
\]
where the matrix for the propagator is
\[
M_{\text{Prop}} = e^{i\phi} \begin{pmatrix} R_{\Theta} & 0 \\ 0 & R_{\Theta} \end{pmatrix}.
\]
where
\[
R_{\Theta} = \begin{pmatrix} \cos \Theta & -\sin \Theta \\ \sin \Theta & \cos \Theta \end{pmatrix},
\]
are the one-way phase shift on the carrier light at frequency \( \omega \) and on modulation sidebands at frequency \( \Omega \), respectively, and
\[
\Theta = \frac{\omega L}{c},
\]
\[
\phi = \frac{\Omega L}{c},
\]
are the reflectivity and transmissivity of the beamsplitter. We consider a beamsplitter with amplitude reflectivity \( \rho \) and \( \tau \) respectively. The beamsplitter transforms the input fields, shown in Fig. 3, according to the matrix equation
\[
\begin{pmatrix} b \\ c \end{pmatrix} = M_{\text{Prop}} \begin{pmatrix} a \\ d \end{pmatrix}.
\]
C. Beamsplitters

Another essential optical element of an interferometer is the beamsplitter. We consider a beamsplitter with amplitude reflectivity and transmissivity \( \rho \) and \( \tau \) respectively. The beamsplitter transforms the input fields, shown in Fig. 3, according to the matrix equation
\[
\begin{pmatrix} b \\ c \end{pmatrix} = M_{\text{Prop}} \begin{pmatrix} a \\ d \end{pmatrix}.
\]
\[
\begin{pmatrix}
  a \\
  c \\
  e
\end{pmatrix}
= M_{BS}
\begin{pmatrix}
  d \\
  b \\
  h
\end{pmatrix},
\]

(22)

where

\[
M_{BS} = \begin{pmatrix}
  -\rho & 0 & 0 & \tau \\
  0 & -\rho & \tau & 0 \\
  0 & \tau & \rho & 0 \\
  \tau & 0 & 0 & \rho
\end{pmatrix}.
\]

(23)

In the presence of optical loss, assuming \(\rho^2 + \sigma^2 + A = 1\), and going through similar arguments to Sec. III A, we simply add a column vector of vacuum fields \(-\sqrt{A}v(i) (i=1,2,3,4)\) onto the right-hand side of Eq. (22).

D. Correlators

The correlator module of the simulation allows for the inclusion of squeezed light or vacuum fields in the interferometer. It is essentially a one-way device: Only fields entering from one direction are transformed; fields entering from the other direction pass through the correlator unmodified. Taking \(a\) to be the input field, the field at the output of the correlator \(b\) is defined by

\[
b = S(r,\phi)a,
\]

(24)

where \(S(r,\phi)\) is the squeeze operator with squeeze factor \(r\) and squeeze angle \(\phi\)

\[
S(r,\phi) = \begin{pmatrix}
  \cosh r + \sinh r \cos 2\phi & \sinh r \sin 2\phi \\
  \sinh r \sin 2\phi & \cosh r - \sinh r \cos 2\phi
\end{pmatrix}.
\]

(25)

IV. RADIATION PRESSURE

Radiation pressure plays an important role in interferometers operating close to or beyond the SQL, since quantum back-action noise must be taken into account. Moreover, radiation-pressure effects can also modify the dynamics of these interferometers [5]. Sideband quadrature fields create amplitude modulations to the carrier field, and the associated power modulation drives the motion of optical elements, which, in turn, phase modulates the carrier, thereby creating sideband quadrature fields.

Details of this sideband-to-sideband conversion depend on the phases (this determines which quadrature gets converted into which) and amplitudes (this determines the conversion strength) of the carrier field propagating in different parts of the interferometer. Therefore, it is necessary to separate the fields into carrier (\(\Omega=0\)) and sideband (\(\Omega \neq 0\)) components at this point. The radiation pressure force due to the carrier field itself is a time-independent force and can be ignored (in reality they will be balanced by a static force exerted on the optical elements, e.g., the pendulum restoring force on a suspended mirror). The effect of interest is the time-dependent part of the force, due to sideband components, which will be the subject of this section. As a foundation, we must first of all calculate the phase and amplitude of the carrier fields at each location. But this can already do by building the general Eq. (2) out of input-output relations of static optical elements, which have already been derived in Sec. III, and solving it.

Before incorporating radiation pressure into the treatment of specific systems, let us study the electromagnetic momentum flux carried by optical fields in the two-photon formalism. In quadrature representation, we decompose the total quadrature field \(E_j^{\text{total}}\) (here \(E_j\) can be \(a, b, c, \) or \(d\) for the configuration in Fig. 1) into the following two terms:

\[
E_j^{\text{total}} = E_j^{\text{carrier}} + E_j^{\text{sb}}.
\]

(26)

The monochromatic carrier field in Eq. (26) can be written more explicitly in terms of power \(I_j\), phase \(\theta_j\) and effective beam area \(A\) as

\[
E_j^{\text{carrier}} = \sqrt{\frac{8\pi I_j}{Ac}} \sin \theta_j,
\]

(27)

while the sideband field can be written as an integral over all sideband frequencies

\[
E_j^{\text{sb}}(t) = \sqrt{\frac{4\pi\hbar\omega}{A}} \int_0^{\infty} d\Omega \frac{\sin \omega}{\omega} \left[ I_j(\Omega)e^{-i\Omega t} + H.c. \right].
\]

(28)

The total momentum flow carried by the field is

\[
\dot{P}_j(\Omega) = \sqrt{\frac{\hbar\omega}{c^2}} D_j^{\text{sb}} j(\Omega),
\]

(30)

where we have defined

\[
D_j = \sqrt{\frac{Ac}{4\pi I_j}} E_j^{\text{carrier}} = \sqrt{2I_j} \left( \frac{\cos \theta_j}{\sin \theta_j} \right)
\]

(31)

as the carrier quadrature field, and \(j(\Omega)\) is the sideband component at angular frequency \(\Omega\).

In the remainder of this section we derive explicit input-output relations for mirrors and beamsplitters, including radiation pressure effects. Our results will be more general than previously obtained results by allowing the carrier fields incident from different ports to have different phases.

A. Mirrors

Let us once again consider the mirror in Fig. 1. Assuming that the mirror behaves as a free particle with mass \(M\) when no radiation-pressure forces are exerted (valid for suspended mirrors when frequencies greater than the pendulum resonant frequency are considered), the Fourier transform for the equation of motion for the mirror is
where \( X \) is the displacement of the mirror induced by all the sideband fields (\( X \) is positive to the left in Fig. 1, and the \( j \) refer to \( a, b, c, d \)). The summation is performed over all the fields entering and exiting the mirror; the coefficients \( \eta_a = \eta_b = -1 \) and \( \eta_c = \eta_d = 1 \) account for the directions of propagation. The displacement of the mirror due to the radiation pressure forces \( X \) can be written explicitly as [see Eq. (30)]

\[
X = \frac{1}{M\Omega^2} \sqrt{\frac{\hbar \omega}{c^2}} \left[ (\mathbf{D}_a^T - \mathbf{D}_b^T) \mathbf{a} + (\mathbf{D}_b^T - \mathbf{D}_c^T) \mathbf{b} \right].
\]

Given a (time-dependent) displacement \( X(t) \) of the mirror, the input-output relation can be written as if \( \dot{X} \leq c \)

\[
E_{b}^\text{total}(t) = -\rho E_{a}^\text{total} \left[ t + \frac{2X(t)}{c} \right] + \tau E_{d}^\text{total}(t)
\]

\[
E_{c}^\text{total}(t) = \tau E_{a}^\text{total}(t) + \rho E_{d}^\text{total} \left[ t - \frac{2X(t)}{c} \right].
\]

Inverting the eigenvalue \( \lambda_4 \) yields a pair of resonant frequencies at

\[
\pm \Omega_M = \pm \frac{8\rho\alpha\sqrt{I_d} \sin(\theta_a - \theta_d)}{MC^2}^{1/2}.
\]

Physically, this resonance comes about because the sideband fields generated by mirror motion can exert radiation pressure back onto the mirror. Let us for a moment consider classical motion of the mirror. As was mentioned after Eq. (37), for any given input carrier field, the sideband field generated upon reflection from the moving mirror is \( \pi/2 \) phase shifted relative to the input carrier, so the sideband will not beat with the reflected carrier to induce any force on the mirror [see Eq. (30)]—force can only be induced by beating this motion-induced sideband field with the transmitted carrier, which must have nonzero amplitude and must have a phase difference other than \( \pi/2 \) relative to the sideband. This explains why the resonant frequency vanishes if either \( \rho = 0 \) or \( \tau = 0 \) (no reflected or transmitted field), or if \( \theta_a - \theta_d = N\pi \) (no phase difference between the two input fields).
Since the mirror is orthogonal to the carrier field about which it is generated, the inverse is just

$$\left[ I + \Pi \left( \begin{array}{c} D^*_a \\ D^*_b \end{array} \right) \left( \begin{array}{cc} D^T_b & -D^T_f \end{array} \right) \right]^{-1}$$

$$= \left[ I - \Pi \left( \begin{array}{c} D^*_a \\ D^*_b \end{array} \right) \left( \begin{array}{cc} D^T_b & -D^T_f \end{array} \right) \right]$$, if $D_a \parallel D_d; 

\text{if } D_a \parallel D_d. 

(43)$$

and

$$\left[ \left( \begin{array}{c} D^*_a \\ D^*_b \end{array} \right) \left( \begin{array}{cc} D^T_b & -D^T_f \end{array} \right) \right]^2 = 0, \text{ if } D_j \parallel D_d. 

(44)$$

(This identity originates from the fact that the sideband field is orthogonal to the carrier field about which it is generated.) Using this fact, we can further simplify the input-output relation to

$$\left( \begin{array}{c} b \\ e \end{array} \right) = \left[ M_{\text{mirror}} - 2 \rho \Pi \left( \begin{array}{c} D^*_a \\ D^*_b \end{array} \right) \left( \begin{array}{cc} \rho & -\tau \\ \tau & \rho \end{array} \right) \right] \left( \begin{array}{c} a \\ d \end{array} \right),$$

if $D_a \parallel D_d.$

(45)

[Here for simplicity we have assumed the mirror to be lossless.] In practice, although Eq. (38) does not give the output fields $b$ and $e$ explicitly in terms of the input fields $a$ and $d$, it can be incorporated to the matrix $M$ (and into $u^{(i)}$, in the presence of optical losses) without any trouble [cf. Eq. (2)]: its inversion will take place automatically when $M^{-1}$ is calculated. [However, doing so will make it impossible to have $-1$ all along the diagonal of $M.$] Alternatively, the variable $X$ may be added to our system of variables, with Eq. (33) providing the additional equation necessary. The equations governing a mirror may then be replaced with Eq. (37) to include the dependence on $X$. In this way, the $-1$ diagonal components are preserved, without the need to invert additional matrices.

**B. Beamsplitter**

Referring to the fields shown in Fig. 3, the displacement due to radiation pressure forces on a beamsplitter (normal to its reflective face) is

$$X_N = X_x + X_y = \frac{1}{\sqrt{2}} \frac{\hbar \omega}{M \Omega^2 c^2} \left[ \begin{array}{cc} D^T_a & -D^T_f \\ D^T_b & -D^T_h \end{array} \right] \left( \begin{array}{c} a \\ c \\ e \\ g \end{array} \right) + \left( \begin{array}{cc} D^T_a & -D^T_f \\ D^T_b & -D^T_h \end{array} \right) \left( \begin{array}{c} d \\ b \\ h \\ f \end{array} \right),$$

(46)

where $X_x$ is the displacement along the $x$ axis and $X_y$ is the displacement along the $y$ axis. Similar to the case of a cavity mirror, this motion induces phase fluctuations on the impinging fields upon reflection, and introduces additional terms in the input-output relation. Following a procedure similar to the one with which we obtain Eq. (37), we get

$$\left( \begin{array}{c} a \\ c \\ e \\ g \end{array} \right) = M_{\text{BS}} \left( \begin{array}{c} d \\ b \\ h \\ f \end{array} \right) - \frac{\sqrt{2} \rho \omega X_N}{c \sqrt{\hbar \omega}} \left( \begin{array}{c} D^*_a \\ D^*_b \\ D^*_h \\ D^*_f \end{array} \right).$$

(47)

Inserting Eq. (46) into Eq. (47) gives

$$\left[ I + \frac{\Pi}{2} \left( \begin{array}{c} D^*_a \\ D^*_b \\ D^*_h \\ D^*_f \end{array} \right) \left( \begin{array}{cc} D^T_a & -D^T_f \\ D^T_b & -D^T_h \end{array} \right) \right] \left( \begin{array}{c} a \\ c \\ e \\ g \end{array} \right) = M_{\text{BS}} - \frac{\Pi}{2} \left( \begin{array}{c} D^*_a \\ D^*_b \\ D^*_h \\ D^*_f \end{array} \right) \left( \begin{array}{cc} D^T_a & -D^T_f \\ D^T_b & -D^T_h \end{array} \right) \left( \begin{array}{c} d \\ b \\ h \\ f \end{array} \right).$$

(48)

Equation (48) is quite similar in nature to Eq. (38); optical losses can also be incorporated in a similar fashion, by adding $-\sqrt{\hbar \omega}/i$, $i=1,2,3,4$ on to its right-hand side, where $\rho^2 + \tau^2 + A = 1$. Again, in the generic case where

$$\left( \begin{array}{cc} D^T_a & -D^T_f \\ D^T_b & -D^T_h \end{array} \right) \left( \begin{array}{c} D^*_a \\ D^*_b \\ D^*_h \\ D^*_f \end{array} \right) \neq 0,$$  

(49)

the matrix on the left-hand side (LHS) of Eq. (48) has eight linearly independent eigenvectors, of which seven have unit eigenvalue, while the eighth has

$$\lambda_8 = 1 + \frac{\Pi}{2} \left( \begin{array}{cc} D^T_a & -D^T_f \\ D^T_b & -D^T_h \end{array} \right) \left( \begin{array}{c} D^*_a \\ D^*_b \\ D^*_h \\ D^*_f \end{array} \right)$$

$$= 1 + \Pi \left( D^T_f D^*_a + D^T_h D^*_b \right) + \frac{4 \rho \tau \omega}{M \Omega^2 c^2} \left( \begin{array}{c} \sqrt{I_d} \sin(\theta_f - \theta_d) \\ \sqrt{I_h} \sin(\theta_h - \theta_d) \end{array} \right),$$

(50)

which corresponds to an optomechanical resonance at angular frequency

$$\pm \Omega_{\text{BS}} = \pm \left[ \frac{4 \rho \tau \omega}{M \Omega^2 c^2} \left( \begin{array}{c} \sqrt{I_d} \sin(\theta_f - \theta_d) \\ \sqrt{I_h} \sin(\theta_h - \theta_d) \end{array} \right) \right]^{1/2}.$$  

(51)

In the special case of
\begin{equation}
(D_c^T D_c^T - D_h^T D_h^T) = 0,
\end{equation}
i.e., all input carrier fields are in phase with each other (modulo \( \pi \)) we get
\begin{equation}
\begin{pmatrix}
a \\
b \\
c \\
d \\
e \\
f
\end{pmatrix} = \left[ M_{B_S} - \rho \Pi \right] \begin{pmatrix}
D_d^* \\
D_b^* \\
D_h^* \\
D_b^T \\
D_c \\
D_f
\end{pmatrix}
\end{equation}
if \( D_h \parallel D_c \parallel D_f \parallel D_h \).

For simplicity, we assume the beamsplitter to be lossless in the above equation. This is particularly true for the beamsplitter in Michelson- and Sagnac-type GW interferometers [11]. Similar to the case of the mirror, for the purposes of simulation, we incorporate the position of the beamsplitter as an additional variable in \( \mathcal{M} \), in order to preserve the \(-1\) diagonal elements and to avoid the inversion of additional matrices.

V. GRAVITATIONAL WAVE SIGNAL AND THE OUTPUT FIELD

A. GW contribution

In our set of optical elements, only optical cavities have significant propagation distances, so we model the effect of GWs by introducing a phase shift to the carrier light as it passes through a cavity. To calculate the propagation of these fields, all that must be done is to add a source term in the equation governing the cavity. Referring to the fields in Fig. 2, the cavity field becomes
\begin{equation}
c = e^{i\phi} R_{c\theta} a - \eta \frac{\omega L h}{2c \sqrt{\hbar \omega}} D^*_c = R_{c\theta} \left[ e^{i\phi} a - \eta \frac{\omega L h}{2c \sqrt{\hbar \omega}} D^*_d \right].
\end{equation}
where \( h \) is the Fourier transform of the GW amplitude. A \( h \) dependent term is also added to the equation relating \( b \) and \( d \) using \( D^*_d \) in place of \( D^*_c \). The parameter \( \eta \) takes values from \(-1\) to \( 1 \) depending on the orientation of the cavity and the polarization state of the incoming GW. For example, for a linearly polarized incoming GW, and for an optimally aligned Michelson interferometer, we have \( \eta = 1 \) for one and \(-1 \) for the other.

It is straightforward to incorporate Eq. (54) into the general equation Eq. (2). In particular, the term containing \( h \) on RHS contributes to the GW part of the general input field \( u \), i.e., to the third term of Eq. (3), with
\begin{equation}
H = - \frac{\eta \omega L h}{2c \sqrt{\hbar \omega}} D^*_c,
\end{equation}
B. Photodetection: signal and noise

For our purposes, the photodetector serves two roles: first, it represents an open port, from which vacuum fluctuations enter the interferometer; second, it determines the measurement point. For the former, the input-output relation of a photodetector, as it contributes to the matrix \( \mathcal{M} \) and the generalized input vector \( u^{(i)} \), is trivial and has been discussed in Sec. II B. Here we focus on the latter. At zero frequency, there is only contribution to \( b \) from the carrier laser, while at nonzero sideband frequencies, the detected fields at a photodetector comprise three components: the gravitational-wave signal, classical laser noise, and noise due to vacuum fluctuations in the detected mode. The outgoing field being detected \( b \) has the general form [see Eqs. (2) and (3)]
\begin{equation}
b = \sum_i [M_i^{-1}]_{b i} \psi^{(i)} + i^{(i)} + H^{(i)b}.
\end{equation}
The summation is performed over all fields. We note that contributions to \( \psi^{(i)} \) exist only for fields that emerge from cavities, and those to \( H^{(i)} \) only for fields that emerge from cavities.

We suppose homodyne detection at quadrature angle \( \xi \) is performed such that the measured field is
\begin{equation}
b_\xi = b_1 \cos \xi + b_2 \sin \xi.
\end{equation}

For a complete simulation, \( \xi \) should be the phase of the carrier that emerges at this port. However, in theoretical studies, we could also assign another value to \( \xi \), assuming that the local-oscillator phase is modified by some other means the simulation does not address.

For the detected field, the quantum noise spectral density is (see, e.g., Sec. III of Ref. [4])
\begin{equation}
(N_{Q})_b = \sum_i \left( \cos \xi \sin \xi \right) T_{b i} S_{b i} T_{b i}^* \left( \cos \xi \sin \xi \right),
\end{equation}

Because \( v_i \) is always proportional to a vacuum field, we have used \( S_{b i} \) to denote the noise spectral density which is identical for all its quadratures. Here we have added the power of different loss contributions, since we assume the vacuum fields to be independent to each other. In general, laser noise is neither quantum limited, nor are the magnitudes of phase and amplitude fluctuations equal; there could also be correlations between the laser amplitude and phase noise, even as the laser field enters the system. Taking these into account, we have a laser noise spectral density of
\begin{equation}
(N_{L})_b = \sum_i \left( \cos \xi \sin \xi \right) T_{b i} S_{L} T_{b i}^* \left( \cos \xi \right),
\end{equation}
where \( l \) corresponds to the input laser field, and
describes noise of the laser as it first enters the interferometer. The displacement
of the arm cavities are a common suspended object, coated
with a high-reflectivity coating on both surfaces and assumed
to have an opaque substrate. Second, this cavity end mirror
object is very light, with a typical mass of 1 g, and is sus-
pended as a pendulum with resonant frequency of about
1 Hz. All remaining optics are assumed to have a mass of
250 g, and are also suspended as pendulums with a resonant
frequency of 1 Hz. Third, the cavities are detuned from reso-
nance.

Testing the simulation with this somewhat unconventional
interferometer configuration served two purposes: (i) It is the
baseline design for an experiment to generate squeezed states
of the electromagnetic field, produced with radiation-
pressure-induced optical forces in an interferometer with
low-mass mirror oscillators and high stored power [13]; and
(ii) the shared end mirror gives rise to unexpected dynamical
effects that prove interesting and instructive to explore, and
are relevant to other high-power interferometers, such as Ad-
vanced LIGO [1]. We note that the shared end mirror has
advantages in terms of mechanical stability and control sys-
tem design, but the desired radiation-pressure effects can be
realized by a configuration with two independent end mirrors
as well.

### VI. APPLICATION TO A COMPLEX INTERFEROMETER

The mathematical formulation described in Secs. II through V was encoded into a simulation program written in
C++. In this section we describe tests of the simulation
code for a complex interferometer configuration, where the
simulation results were compared with analytic calculations.

The interferometer configuration is shown in Fig. 5, and
in Fig. 6 we show fields propagating in the interferometer as
well as modes of motion of the mirrors. The interferometer is
similar to that used in GW detection: a Michelson inter-
ferometer with Fabry-Pérot cavities in each arm. All the mirrors
of the interferometer are suspended as pendulums. Power
recycling [12] is optional and is not included here. The con-
figuration shown has a few unusual features compared with a
conventional interferometer, however. First, the end mirrors
of the arm cavities are a common suspended object, coated

\[ S_L = \begin{pmatrix} S_{11} & S_{12} \\ S_{12} & S_{22} \end{pmatrix} \]  

(60)

\[ H_b = \sum_i (\cos \xi \sin \xi) T_{b,i} H^0. \]  

(61)

Note that GW contributions from different parts of the sys-
tem add up coherently. The displacement (strain) noise spec-
tral density from quantum noise is then given by

\[ S_b = \frac{N_0^2 + N_L^2}{|H|^2}. \]  

(62)

### A. Ideal optical springs

In this section we study analytically a crucial component of
the interferometer design: the optical spring effect, es-
specially in the case of two identical detuned cavities with a
common end mirror. The input-output relation of this system
can be obtained by carrying out our generic procedure ana-
lytically. In doing so, we extend previous results in Refs.
[5,14] to include two features. First, we consider motions of all
three mirrors, with mass of the input mirrors different
from that of the common end mirror. Second, in our system
the carrier phases incident on mirrors are different; under
such a circumstance, formulas developed in Sec. IV are non-
trivial extensions to existing ones.

In order to make results intuitively understandable, we
consider only the ideal system, with the two input mirrors

completely identical, the common mirror perfectly reflective on both sides, the two cavities having exactly the same lengths, the carrier incident on both input mirrors having equal amplitude and phase, and with a perfect beamsplitter. We also ignore the free pendulum frequency, and consider the test masses to be free. Similar to previous studies, we assume a high-finesse cavity and ignore the interaction between the motion of the input mirror and the carrier light outside the cavity. We retain terms only to the leading order in $\epsilon L/c$, $\lambda L/c$, and $\Omega L/c$, where $L$ is the cavity length, $c$ is the speed of light, $\Omega$ is the sideband frequency, and $(\lambda \pm i \epsilon)$ is the complex optical resonant frequency of the cavity with fixed mirrors [\(\lambda\) denotes the resonant frequency and $\epsilon$ the bandwidth, defined in Table II; and we ignore end-mirror loss].

1. Differential mode

With the above assumptions, the differential optical mode couples only to differential modes of mirror motion: those with the two input masses moving such that $x_A = -x_B = x_D$, and arbitrary $x_m$ [see Fig. 6]; such modes form a two-dimensional subspace of all possible motions of the three mirrors. In the ideal case, we only need to study this mode. The differential input-output relation is given by

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \frac{1}{\mathcal{M}_D} \mathbf{R}_D \left[ \mathbf{C}_D \mathbf{R}_a \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} + \mathbf{s}_D \begin{bmatrix} x_m^{(0)} + x_D^{(0)} \end{bmatrix} \right],$$

(63)

with

$$\mathbf{C}_D = \begin{bmatrix} - (\Omega^2 - \lambda^2 + \epsilon^2) \Omega^2 - \lambda \epsilon \Omega^2 & 2 \epsilon \lambda \Omega^2 \\ - 2 \epsilon \lambda \Omega^2 + 2 \epsilon \epsilon \Omega^2 & -(\Omega^2 - \lambda^2 + \epsilon^2) \Omega^2 - \lambda \epsilon \Omega^2 \end{bmatrix},$$

$$\mathbf{s}_D = \frac{2 \sqrt{\epsilon \epsilon \Omega^2}}{L h_{SQL}^D} \begin{bmatrix} \lambda \\ - \epsilon + i \Omega \end{bmatrix},$$

(64)

and

Here $x_D^{(0)}$ is the motion of a free end mirror with the same mass, $x_D^{(0)}$ is the free differential motion of the input mirrors ($x_A^{(0)} = -x_B^{(0)} = x_D^{(0)}$); $\alpha = \arctan(\lambda / \epsilon)$ is the carrier phase at the end mirror. The carrier incident on the input mirrors has phase 0, the carrier inside the cavity, leaving the input mirror has phase $\alpha - \phi$, while the carrier inside the cavity entering the input mirror has phase $\alpha + \phi$. The quantity $h_{SQL}^D$ is the free-mass standard quantum limit associated with the differential mode, given by

$$h_{SQL}^D = \sqrt{\frac{2 \hbar}{\mu_D \Omega^2 L^2}}, \quad \mu_D = 2 m L / (m + 2 L).$$

(66)

The quantity $t_D$, defined by

$$t_D = \frac{8 \omega_D I_c}{\mu_D L c},$$

(67)

measures the strength of optomechanical coupling [notice the dependence on carrier intensity $I_c$ and the inverse dependence on the effective mass of the differential mode mechanical oscillator $\mu_D$]. Roots of $\mathcal{M}_D$ are the (complex) resonant frequencies of the coupled optomechanical system. From $t_D$ we define a characteristic frequency

$$\Theta_D = \sqrt{t_D \lambda / (\epsilon^2 + \lambda^2)},$$

(68)

For systems with $\Theta_D \ll \epsilon$, the two resonances are well separated, and are given approximately by $\pm \Theta_D$ [mechanical frequency due to optical spring and $(\pm \lambda - i \epsilon)$ [optical resonant frequency], respectively—this is indeed the regime in which we construct our experiment.

The differential optical mode couples to a two-dimensional subspace of all possible motions of the three mirrors. It is instructive to look at the motion of separate mirrors, in the regime of $\Omega \ll \epsilon$, i.e. for sideband frequencies $\Omega$ well within the linewidth of the cavities:

$$\begin{bmatrix} x_m \\ x_D \end{bmatrix} = \frac{1}{\Theta_D^2 - \Omega^2} \begin{bmatrix} \Theta_D^2 - \Omega^2 & -\Theta_D^2 \\ -\Theta_D^2 & \Theta_D^2 \frac{\lambda^2}{\lambda^2 + 1} - \Omega^2 \frac{\lambda^2}{\lambda^2 + 1} \end{bmatrix} \begin{bmatrix} x_m^{(0)} \\ x_D^{(0)} \end{bmatrix},$$

(69)

Here we have defined $\lambda^2 = 2 M / m$. From Eq. (69), we conclude immediately that
This change in response is exactly what happens when a free test particle is connected to a spring with mechanical resonant frequency $\Theta_D$. Equation (70) reveals a crucial advantage of the optical spring—that the response of the cavity length to external disturbances (e.g., driven by seismic and/or thermal forces) is greatly suppressed from the corresponding value for free-mass systems. Theoretically, this suppression is present even when a mechanical spring is used. However, mechanical springs introduce thermal noise, usually of much higher magnitude due to the intrinsic mechanical loss [14, 15].

It is interesting to notice that the suppression of total cavity length fluctuations is achieved collectively by the end mirror and the input mirror. As we see from Eq. (69), [in the case of large $\Lambda$], the motion of the end mirrors $x_m$ is suppressed from its free mass value by the factor in Eq. (70), while the motion of the input mirrors $x_D$ is not influenced by the spring, since it is relatively massive. Fortunately, through the $(1,2)$ component of the matrix on the RHS of Eq. (69), this motion of the input mirror is imposed onto the end mirror with opposite sign, again suppressing the total cavity length fluctuations.

Now let us restrict ourselves to the regime of $\Omega < \Theta_D < \epsilon$, and study the quantum fluctuations and classical component of the output field (due to classical disturbances to the mirrors). As we shall see shortly, this regime has two crucial features: (i) the response of the output field to $x_m^{(0)} + x_D^{(0)}$, and thus length fluctuations due to seismic and thermal noise, are greatly suppressed by the optical spring and (ii) the output squeezed state is frequency independent.

For quantum fluctuations, we have

$$\frac{C_D}{M_D} \rightarrow \begin{pmatrix} -1 & 0 \\ 2\epsilon/\lambda & -1 \end{pmatrix},$$

(71)

which is frequency independent. It is straightforward to derive that the quantum noise spectrum in the $b_\xi = b_1 \cos \zeta + b_2 \sin \zeta$ quadrature [cf. Eq. (58)]

$$S_\zeta \rightarrow 1 + \frac{2\epsilon^2}{\lambda^2} - 2\sqrt{\frac{\epsilon^2}{\lambda^2} + \frac{\epsilon^2}{\lambda^2}} \cos(2\zeta - 3\alpha).$$

(72)

In particular, terms in $\epsilon/\lambda$ are associated with squeezing, where the constant power squeeze factor $e^{2\zeta}$ ($q > 0$) is given by

$$\sin q = |\epsilon/\lambda|.$$  

(73)

The minimum noise spectral density ($S_\zeta = e^{-2\zeta}$) is reached at $\zeta = 3\alpha/2$, while at $\zeta = \alpha$ and $2\alpha$ the noise spectrum is equal to the vacuum level ($S_\zeta = 1$). Values of $\epsilon/\lambda$ corresponding to several power squeeze factors are listed in Table III. As shown, $\epsilon$ and $\lambda$ will not differ by a factor of more than $-2$, for typically desired squeeze factors.

Now for the classical component, given by the second term in Eq. (63), we have

<table>
<thead>
<tr>
<th>Squeeze factor (dB)</th>
<th>3</th>
<th>7</th>
<th>10</th>
<th>20</th>

</thead>
<tbody>
<tr>
<td>$\epsilon/\lambda$</td>
<td>0.58</td>
<td>1.13</td>
<td>1.42</td>
<td>2.12</td>
</tr>
</tbody>
</table>

(74)

This means the entire signal due to differential displacement $x_m^{(0)} + x_D^{(0)}$ is in the single quadrature $\zeta = 2\alpha + \pi/2$, and there is no $x_m^{(0)} + x_D^{(0)}$ signal in the $\zeta = 2\alpha$ quadrature. Interestingly, the quantum noise in this quadrature is flat at vacuum level. In addition, since $h_{SQL} = \Omega$, the response of $b_1$ to $x_m^{(0)} + x_D^{(0)}$ is proportional to $\Omega^2$ at this regime—therefore not only the motion, but also the output field, has a suppressed response to thermal and seismic noises. Note here that the suppression factor is proportional to $\sqrt{\lambda}$ (since $\theta_2 \propto \sqrt{\lambda} = \sqrt{\alpha}$)—because motion is suppressed by $L_s$, while the optical sensing of mirror motion is enhanced by $L_s$. Now suppose we introduce a noisy force which induces a spectral density $S_{\zeta}^{\prime}$ on a free mass, then the output classical noise will be

$$S_{\zeta}^{\prime} = 4 \frac{\epsilon^2}{\Theta_D^2} \frac{\sin(\zeta - 2\alpha)}{L_s^2 h_{SQL}^2}.$$  

(75)

At the minimum quantum noise quadrature, $\zeta = 3\alpha/2$, we have

$$S_{3\alpha/2}^{\prime} = 2 \frac{\epsilon^2}{\lambda^2} \left[ 1 - \frac{\epsilon}{\sqrt{\lambda^2 + \epsilon^2}} \right] \frac{\Omega^2}{\Theta_D^2} \frac{S_s}{L_s^2 h_{SQL}^2} \leq 0.6 \frac{\Omega^2}{\Theta_D^2} \frac{S_s}{L_s^2 h_{SQL}^2},$$  

(76)

where the inequality is obtained by taking maximum over all $\epsilon$ and $\lambda$. We note that because of the suppression factor $\Omega^2/\Theta^2$, the classical noise $S_{\zeta}^{\prime}$ can be much higher than the free-mass standard quantum limit while still allowing the interferometer to generate squeezed vacuum!

2. Common mode

We now consider the common optical mode, which couples with motion of the input mirrors corresponding to $x_A = x_B = x_C$. This mode is irrelevant to an ideal interferometer with identical arms and perfect contrast. In reality, however, the common mode will influence the output via couplings induced by differences (mismatch) between the two cavities, for example. Such effects can be quite important near the common-mode optomechanical resonance.

The input-output relation of the common mode, similar to that of the differential mode [cf. Eq. (63)], is given by

$$\begin{pmatrix} y_1 \\ y_2 \end{pmatrix} = \frac{1}{M_C} \begin{pmatrix} R_a & C_C \end{pmatrix} \begin{pmatrix} x_1^{(0)} \\ x_2^{(0)} \end{pmatrix} + \begin{pmatrix} s_{C1}^{(0)} \\ s_{C2}^{(0)} \end{pmatrix},$$

(77)

with [cf. Eq. (64)]
The quantity $\lambda_{CM}$ is given by [cf. Eq. (67)]

$$\lambda_{CM} = \frac{8\omega_{0}\epsilon}{\mu_{c}L_{c}}.$$  

(81)

For the common mode, we have an optomechanical resonant frequency of [cf. Eq. (68)]

$$\Theta_{C} = \sqrt{\omega_{C}^{2} + \lambda_{C}^{2}}, \quad \text{if} \quad \Theta_{C} \ll \epsilon.$$  

(82)

This frequency is in general much lower than its differential-mode counterpart, with

$$\Theta_{C} = \sqrt{\omega_{D}^{2} + \lambda_{C}^{2}} = \sqrt{\frac{m^{2} + 2M}{m^{2} + 2M}}.$$  

(83)

**B. Laser coupling to the antisymmetric port due to mismatch**

Mismatch between the optical parameters of the two arm cavities, as well as imbalance in the beamsplitter reflection/transmission ratio and imperfect contrast of the Michelson interferometer, can couple the carrier and also the noise sidebands on the laser to the differential detection port. For each arm, $A$ and $B$, we denote the true value of the $k$th quantity by its nominal value plus contributions due to imperfections, i.e.,

$$X_{(k)A,B} = X_{(k)} \pm \frac{1}{2} \Delta X_{(k)}.$$  

(84)

Here the index $k$ refers to the type of imperfection being considered. The beamsplitter asymmetry is characterized by

$$\Delta_{BS} = r_{BS}^{2} - r_{BS}^{2}.$$  

(85)

Michelson imperfections can be characterized by the difference in the phase shifts and losses when light travels from the beamsplitter to the input mirrors of the two arms

$$\alpha_{MA,B} = \alpha_{M} \pm \frac{1}{2} \Delta \alpha_{M}, \quad \epsilon_{MA,B} = \epsilon_{M} \pm \frac{1}{2} \Delta \epsilon_{M}.$$  

(86)

In addition to $\Delta_{BS}$, $\Delta \alpha_{M}$, and $\Delta \epsilon_{M}$, which concern the beamsplitter, we consider the following contributions to mismatch between the arms

$$T_{iA,B} = T_{i} \pm \frac{1}{2} \Delta T_{i}. $$  

(87)

that is, mismatch between input mirror power transmissivities, end mirror losses, and cavity detuning, respectively. We replace these with the following more convenient quantities:

$$\frac{\Delta \epsilon}{\epsilon} = \frac{\Delta \tau}{T_{i} + T_{e}}, \quad \frac{\Delta \epsilon_{L}}{\epsilon} = \frac{\Delta \epsilon_{S}}{T_{i} + T_{e}}, \quad \frac{\Delta \lambda}{\lambda} = \frac{\Delta \phi}{\phi}.$$  

(90)

[See Table II for definitions of $\epsilon$, $\epsilon_{L}$, and $\lambda$.]

In the remainder of this section, we give the transfer functions from the carrier light (dc), laser amplitude fluctuations, and laser phase fluctuations to the differential output port, to first order in the mismatch (recall that ideally, in the absence of imperfections, these common-mode inputs do not appear in the differential output port). We keep our formulas to the leading order in $(\Omega L_{c}, \epsilon L_{c}, \lambda L_{c}/\epsilon)$, and ignore the averaged losses $\epsilon_{e}$ and $\epsilon_{M}$ (but not $\Delta \epsilon_{e}$ and $\Delta \epsilon_{M}$). We refer to this as the leading-order approximation. Furthermore, in order to keep the analytical results understandable, we work only in the regime of $(\Omega, \Theta_{C}) \ll (\Theta_{D}, \lambda, \epsilon)$, which we shall refer to as the low-frequency regime.

Definitions and assumed values for $\Delta_{BS}, \Delta \alpha_{M}, \Delta \epsilon_{M}, \Delta \tau, \Delta \phi$, and $\Delta \epsilon$ are given in Table I.

**1. Carrier**

The transfer function from the carrier to the differential output can be written as

$$\sum_{k} \Delta_{(k)} C_{(k)} \left( \begin{array}{c} \cos \phi_{(k)} \\ \sin \phi_{(k)} \end{array} \right),$$  

(91)

where definitions of $\Delta_{(k)}$, values of $C_{(k)}$ and $\phi_{(k)}$ are listed in Table IV, assuming the carrier at the beamsplitter is in the first (amplitude) quadrature.

Contributions listed in Table IV can all be obtained from simple considerations. First, since each field that interferes at the beamsplitter is scaled by one transmission and one reflection coefficient factor, $\Delta_{BS}$ does not contribute to the output carrier light at the differential port. Then, for all mismatches except the loss, one only has to notice that when the arm cavities are lossless, carrier light with amplitude $D$ and phase $\varphi = 0$ returns to the beamsplitter with amplitude reduced to $(1 - \epsilon_{M})$, and quadrature rotated by $2 \alpha + 2 \Delta \alpha_{M}$. As a consequence, the differential output port gets $(D/2)(-\Delta \epsilon_{M}) = -(-\Delta \epsilon_{M}/2)D$ in the $\varphi = 2 \alpha$ quadrature (factor of 2 due to the beamsplitter), and

$$(D/2)\Delta[2 \alpha + \Delta \alpha_{M}] = \left\{ \frac{\epsilon \lambda}{\epsilon^{2} + \lambda^{2}} \left( \frac{\Delta \epsilon}{\epsilon} + \frac{\Delta \lambda}{\lambda} \right) + \Delta \alpha_{M} \right\} D$$  

(92)

in the orthogonal quadrature $\varphi = 2 \alpha + \pi/2$. The effect of the loss mismatch can be understood when we decompose the (complex) reflectivity of the cavity into a sum of two components.
sidering the different ways $\varphi$ appears in Eqs. (91) and (95), this means the phase noise coupled to the differential output port remains orthogonal to the carrier. This can be argued for easily: Since phase modulations on the carrier do not drive mirror motion, the propagation of phase noise is not affected by the optical spring. Amplitude modulations, on the other hand, do drive mirror motion and therefore should couple to the differential port in a dramatically different way. We tabulate the quantities $N_{N_{(k)}^P}$ and $\varphi_{(k)}^P$ in Table V, from which we can see that the amplitude-noise coupling has features around the common-mode optical-spring resonant frequency $\Theta_C$.

3. Evading laser noise by artificial asymmetry

For realistically achievable symmetry between the two arms, laser noises turn out to be the dominant noise source to our squeezer. Here we discuss a way of mitigating laser noise coupling by introducing artificial asymmetries. According to the approximate results (in the leading-order approximation and low-frequency regime) obtained in the previous section, both amplitude and phase noise emerge from single quadratures (as vector sums of contributions from different mechanisms). We can, therefore, eliminate the laser noise totally, up to this order, if we make both of them emerge from the same quadrature $\zeta+\pi/2$, and make sure that the orthogonal quadrature $\zeta$ has a subvacuum noise spectrum. At our disposal are two asymmetries that we can adjust manually: $\Delta\alpha_M$ and $\Delta\epsilon_M$.

At any given sideband frequency $\Omega$, for a generic set of other asymmetries, it is always possible to make both laser noise sources emerge at the $\zeta+\pi/2$ quadrature (and, therefore, to vanish at the $\zeta$ quadrature), by adjusting $\Delta\alpha_M$ and $\Delta\epsilon_M$, if the following nondegeneracy condition is satisfied

$$\Delta_{\text{laser}}(\Omega, \zeta) = \det \begin{bmatrix} \sin(\varphi_{(m)}^A - \zeta)N_{(m)}^{A*} & \sin(\varphi_{(m)}^A - \zeta)N_{(m)}^{A*} \\ \sin(\varphi_{(n)}^P - \zeta)N_{(n)}^{P*} & \sin(\varphi_{(n)}^P - \zeta)N_{(n)}^{P*} \end{bmatrix} \neq 0.$$  

[See Eq. (95).]

According to Tables IV and V, laser phase noise emerges in a frequency-independent quadrature, but the amplitude noise does not. This means the elimination of laser noise must be frequency dependent, and we can only choose one particular frequency for perfect laser noise evasion. However, if $\Omega \gg \Theta_C$ is also satisfied, then the frequency dependence goes away. We consider this special case, and choose a detection quadrature of $\zeta=3\alpha/2$, i.e., the one with minimum quantum noise. From Tables IV and V, we get

$$\Delta_{\text{laser}}\left(\Omega, \frac{3}{2}\alpha\right)|_{\Theta_C=0} = -\frac{\epsilon}{4\sqrt{\epsilon^2 + \lambda^2}} \not= 0.$$  

(98)

Since the carrier always emerges $\pi/2$ away from the phase noise, it emerges in exactly the same quadrature we propose to detect. In this way, the laser-noise-avoiding squeezer always produces squeezed light with amplitude squeezing.

Finally, we note that, due to possible higher-order corrections, laser noise evasion may not be as perfect as predicted
by our first-order approximation, even at a single frequency. The amount of residual laser noise, as well as the exact level of the deliberate asymmetries we introduce, must be given by a more accurate calculation.

C. Comparison between analytical calculations and numerical simulations

In Table I, we list the parameters used in modeling our interferometer. An important feature of the numerical code is that it can handle imperfections in the optics quite naturally, while for analytical techniques the solution becomes complicated rather dramatically when more ingredients are added. To fully test this feature, we constructed a test case with realistic imperfections. The imperfections included were those mentioned in Sec. VI B. Using the parameters listed in Table I, we calculate the noise at the differential port due to quantum fluctuations entering from this port and from lossy mirrors, as well as laser amplitude and phase fluctuations entering from the symmetric port.

In Fig. 7, we show the calculated noise levels from numerical simulations in curves, while those from the analytical treatment are shown as solid points. The agreement between the two sets of calculations is reassuring. Now we discuss these noise spectrum in more details. In the upper panel of Fig. 7, we plot noises due to vacuum fluctuations entering from the dark port (blue curve and points), and due to vacuum fluctuations entering from mirror losses (green curve and points). In both results, there is a rather dramatic resonant feature around the differential-mode optical-spring resonant frequency, at $\Theta_{p}=8$ kHz, as can be expected from Sec. VI A. The rather weak but still noticeable feature around the common-mode optical-spring resonant frequency $\Theta_{C}=360$ Hz is solely due to optical parameter mismatch. In the lower panel, we show laser amplitude (green curve and dots) and phase (blue curve and points) noises; we have introduced artificial asymmetries $\alpha_{M}$ and $\epsilon_{M}$, with values obtained empirically using the numerical simulation code, such that both laser noise sources are evaded to a roughly maximal extent at 1 kHz. For this reason, contributions to the results shown here are largely higher order, and we cannot hope to explain them using results obtained in Sec. VI B. Here we do observe dramatic features around both the differential-mode and the common-mode optical-spring resonances.

Results in Fig. 7 are also of great significance for a practical reason: They show that the vacuum modes exiting the interferometer are squeezed by a large factor even in the presence of realistic estimates for optical losses (upper panel) and laser amplitude and phase noise (lower panel).

VII. SUMMARY AND CONCLUSIONS

The main purpose of this work was to develop a mathematical framework for the simulation of quantum fields in a complex interferometer that includes radiation pressure effects. We work in the linear regime around the operation point of this interferometer; in this regime, after adopting the Heisenberg picture of quantum mechanics, the quantum equations of motion (Heisenberg operators) of observables are identical to classical ones.

During the development of this framework, we augmented previous treatments of mirrors (and beamsplitters) by allowing the carrier phases at the four (eight) ports to be different. This extension gives rise to the optical spring effect even without detuned optical cavities.

Based on this mathematical framework, we developed a simulation code that can allow arbitrary optical topologies,
and applied it to a specific example of the interferometer shown in Fig. 5. This interferometer was shown to be capable of squeezing the vacuum modes that enter— and subsequently exit—the differential port of the beamsplitter. We introduced optical spring effects by detuning the arm cavities as a means of mitigating the detrimental effects of thermal noise. We study not only the quantum noise, but also laser noise couplings from the symmetric (input or bright) port to the output (antisymmetric or dark) port. Good agreement was found between numerical results given by this code and analytical ones derived independently. This agreement makes us confident that the simulation is working correctly for this rather complex interferometer.

During our study of the laser noise couplings, we found a method of evading the laser noise by introducing artificial but controlled asymmetries. This is crucial for the practical implementation of this interferometer, and is likely to find applications in many other experiments.

Our simulation code is now being used in the detailed optical design of the advanced LIGO interferometer. We also envisage the following extensions to the code in the near future:

- Allowing multiple carrier or rf sidebands, which may be relevant to the modeling of squeezing experiments that use nonlinear optical media, e.g., crystals, as well as the modeling of error signals for control systems.
- Incorporating the modeling of servo loops. Here we may rely on the input from quantum control theory as to whether and how realistically a Heisenberg treatment can describe a electro-optical feedback system.
- Allowing nonlinear media or other elements with “custom” dispersion relations.

ACKNOWLEDGMENTS

We thank our colleagues at the LIGO Laboratory, especially Keisuke Goda and David Ottaway, for stimulating discussions. We gratefully acknowledge support from National Science Foundation Grant Nos. PHY-0107417, PHY-0300345 and (for Y.C.) PHY-0099568. Y.C.’s research was also supported by the David and Barbara Groce Fund at the San Diego Foundation, as well as the Alexander von Humboldt Foundations’s Sofja Kovalevskaja Programme (funded by the German Federal Ministry of Education and Research). Y.C. thanks the MIT LIGO Laboratory for support and hospitality during his stay.

APPENDIX: TWO-PHOTON QUANTUM OPTICAL FORMALISM

We use the two-photon formalism developed by Caves and Schumaker [9] and Shumaker and Caves [10] to describe GW interferometers with significant radiation-pressure effects. In this formalism, any quasimonochromatic optical field $A$ with frequency near the carrier frequency $\omega$ is written as

$$E(t) = E_1(t)\cos(\omega t) + E_2(t)\sin(\omega t)$$

$$= (\cos \omega t \quad \sin \omega t) \begin{pmatrix} E_1(t) \\ E_2(t) \end{pmatrix},$$

(A1)

where $E_1(t)$ and $E_2(t)$ are called quadrature fields, which vary at time scales much longer than that of the optical oscillation, $1/\omega$. The quadrature formalism replaces $E(t)$ by
The dc components of $E_{1,2}(t)$ can be regarded as monochromatic carrier light. In particular, carrier light with amplitude $De^{i\varphi}$ is represented as

$$D e^{i\varphi} \leftrightarrow (De^{i\varphi}) e^{-i\omega t} \leftrightarrow D \begin{pmatrix} \cos \varphi \\ \sin \varphi \end{pmatrix}. \quad (A3)$$

AC components of $E_{1,2}(t)$, which we denote by $\tilde{A}_{1,2}(t)$, are called sideband fields, which are usually more convenient to study once transformed into the frequency domain,

$$\tilde{A}_{1,2}(\Omega) = \int_{-\infty}^{+\infty} A_{1,2}(t) e^{i\Omega t} dt. \quad (A4)$$

In quantum two-photon optics, it is convenient to use a particular normalization for sideband fields

$$A_{1,2}(\Omega) = \sqrt{\frac{4\pi\hbar\omega}{Ac}} \int_{0}^{+\infty} d\Omega' [a_{1,2}(\Omega) e^{-i\Omega t} + \text{H.c.}]. \quad (A5)$$

In this way, we have a convenient set of commutation relations (for $\Omega \approx \omega$) [9,10]

$$[a_{1,2}, a_{1,2}^\dagger] = [a_{1}, a_{1}^\dagger] = [a_{2}, a_{2}^\dagger] = 0. \quad (A6a)$$

$$[a_{1}, a_{2}^\dagger] = a_{2}, a_{1}^\dagger] = 2\pi i \delta(\Omega - \Omega'). \quad (A6b)$$

Here we have denoted $a_{1,2} = a_{1,2}(\Omega)$, $a_{1,2}' = a_{1,2}(\Omega')$.
