(Received 27 March 2012; published 12 September 2012)

Current searches for compact binary mergers by ground-based gravitational-wave detectors assume for simplicity the two bodies are not spinning. If the binary contains compact objects with significant spin, then this can reduce the sensitivity of these searches, particularly for black hole-neutron star binaries. In this paper we investigate the effect of neglecting precession on the sensitivity of searches for spinning binaries using nonspinning waveform models. We demonstrate that in the sensitive band of Advanced LIGO, the angle between the binary’s orbital angular momentum and its total angular momentum is approximately constant. Under this constant precession cone approximation, we show that the gravitational-wave phase is modulation in two ways: a secular increase of the gravitational-wave phase due to precession and an oscillation around this secular increase. We show that this secular evolution occurs precisely three ways, corresponding to physically different apparent evolutions of the binary’s precession about the line of sight. We estimate the best possible fitting factor between any nonprecessing template model and a single precessing signal, in the limit of a constant precession cone. Our closed-form estimate of the fitting factor depends only the geometry of the in-band precession cone; it does not depend explicitly on binary parameters, detector response, or details of either signal model. The precessing black hole-neutron star waveforms least accurately matched by nonspinning waveforms correspond to viewing geometries where the precession cone sweeps the orbital plane repeatedly across the line of sight, in an unfavorable polarization alignment.

I. INTRODUCTION

Ground-based gravitational-wave detector networks (notably LIGO [1–3] and Virgo [4,5]) have performed several searches for the inspiral and merger of binaries containing black holes (BH) and neutron stars (NS) [6–15]. The coalescence of NS-NS, BH-NS, and BH-BH binaries are the most promising sources of gravitational waves for these networks [16]. For the lowest-mass compact binaries \( M = m_1 + m_2 \leq 15M_\odot \), the response of the detector to a binary merger with arbitrary masses and spins is well understood [17–23]. To identify the presence and properties of a signal, the classic approach to data analysis on nonspinning binaries has been matched filtering, linearly projecting the data against each member of a template bank: a discrete array of signal models, spaced to cover all possibilities with minimal intertemplate and template-signal mismatch [24–28]. For nonspinning binaries, the templates needed lie in the two-dimensional signal manifold itself (i.e., in \( m_1 \), \( m_2 \) or more naturally in the chirp mass \( \mathcal{M}_c = M \eta^{3/5} \) and symmetric mass ratio \( \eta = m_1 m_2/M^2 \)) [24,25,27]. For spinning binaries with more physical degrees of freedom, the added physical parameters require either (i) exact template banks that are impractically large, with a significant increase in computational burden and false alarm rate; or (ii) the use of an approximate detection template family, whose waveforms usually at best imperfectly approximate the target waveforms [18–21,29] but whose template banks are smaller and better understood. Though the more generic BCV detection template family [20] has been applied in previous searches for spinning systems [10,30], recent studies suggest that it is no more effective than the nonspinning template bank for low-mass single-spin binaries [26]. Current templated searches for the gravitational-wave signature of low-mass merging binaries are performed using this simple nonspinning bank [12,13,15]. However, these results show that searching for generic spinning binaries with a nonspinning search is suboptimal and further work is needed to construct an optimal search for spinning binaries in Advanced LIGO and Advanced Virgo. Such a search may involve, e.g., a hierarchical combination of a nonspinning search and a search using spinning templates, or a nonspinning search in some regions of the parameter space, with targeted spinning searches in others. To devise the correct strategy, it is essential to understand where and why advanced-detector searches will lose signal-to-noise ratio when searching for spinning binaries using nonspinning waveforms; this is the goal of this paper.

Recent work on binaries where the spin is aligned with the orbital angular momentum has demonstrated that advanced detectors are more sensitive to the effects of spin on the orbital phase than first generation detectors [31].
However, it has been shown that a slightly more generic search would recover all nonprecessing signals well by capturing the phase evolution of generic nonprecessing sources [31]. Nonetheless, a noticeable fraction of these spinning binary mass, spin, and orientation parameters are at best poorly matched with nonspinning and even generic nonprecessing templates, some with match lower than ≈ 0.6. These large mismatches occur because nonspinning templates cannot capture the effects of spin.

This paper is concerned with binaries where the spin and angular momentum of the binary are not aligned. This induces precession, causing the orbital angular momentum direction \( \vec{L} \) to change with time. Because the instantaneous beam pattern of the gravitational-wave emission is oriented along \( \vec{L} \), the changing angle between \( \vec{L} \) and the line of sight \( \hat{n} \) produces large amplitude and phase modulations that are absent in nonprecessing signals. Poor matches with nonspinning templates are disproportionately concentrated in systems that exhibit precession: systems with significant spin-orbit misalignment and asymmetric mass ratio. Conversely, binaries with tight spin-orbit alignment or simply limited misalignment and asymmetric mass ratio. The second way that precession modifies the signal is via a secular change of the gravitational-wave phase. In addition to the effect of orbital dynamics, the gravitational-wave signal also accumulates a geometrical phase, a fraction of the “precession phase” of \( L \) about \( \hat{J} \). This second epoch of transitional precession (typically when \( |\vec{L}| \approx |\vec{S}| \); see Ref. [35]), these binaries usually undergo simple precession, where the orbital angular momentum precesses around the total angular momentum with an ever-increasing opening angle [35]. By investigating the spin evolution equations of Apostolatos et al. [35], we find that the opening angle of the precession cone (i.e., the angle between the total angular momentum \( \vec{J} \) and the orbital angular momentum \( \vec{L} \)) does not expand significantly while the binary’s signal is in the detector’s sensitive band. We perform analytic studies under the assumption that this opening angle is exactly constant; we call this the constant precession cone approximation. We find the gravitational-wave phasing is modulated in two ways. The first way that precession modifies the signal is via a secular change of the gravitational-wave phase. In addition to the effect of orbital dynamics, the gravitational-wave signal also accumulates a geometrical phase, a fraction of the “precession phase” of \( \vec{L} \) about \( \vec{J} \). Previous work has demonstrated that precession induces a secular change in the phase accumulating over each precession cycle, both in post-Newtonian (PN) studies [19,35] and in numerical simulations of general relativity [36]. Though long recognized, this factor is not included in standard analytic nonprecessing template models [32–34].

We furthermore find this secular evolution occurs in three different ways, corresponding to physically different apparent evolutions of the precession about the line of sight. These three ways correspond precisely to whether the cone swept out by \( \vec{L} \) encloses zero, one, or two of the “null lines,” which are the directions that produce exactly zero instantaneous response in the detector. The three regions correspond to whether zero, one, or both directions are enclosed by the path swept out by \( \vec{L} \)—henceforth, the “precession cone.” Each type of configuration leads to a unique effect on the phasing of the binary. If you are within one of the regions, you accumulate secular phase at the same rate.

The second way that precession modifies the signal is by introducing phase (and amplitude) modulations, on top of secular evolution. These modulations cannot be captured by a nonprecessing template. A nonprecessing signal model will therefore not match a precessing signal optimally. Moreover, the highest possible mismatch between a precessing signal and nonprecessing model can be estimated geometrically. In other words, our calculation tells us how easily a nonprecessing search can find each particular precessing signal. For simplicity, we perform our analytic studies assuming a source directly overhead a single detector. Our results will be generalized to a full network in a future analysis. Though simplified, our study is nonetheless directly applicable to real searches. Moreover, given the complexity of realistic searches, special cases where searches have well-understood performance provide invaluable tools for code validation and search calibration. Past, present, and future searches therefore benefit from the goal of this paper: a simple model for how well nonspinning searches recover most spinning, precessing low-mass binaries.

We will perform a detailed point-by-point numerical comparison of this expression to a large-scale Monte Carlo study of synthentic searches in a subsequent publication. To compare with existing results in the literature, however, we apply our purely analytic results to randomly selected binary parameters. We find our expressions quantitatively agree with previous Monte Carlo studies of nonprecessing searches [20,37], including recent investigations that include both mass and aligned spin as parameters [31]. For instance, adopting the same spin distribution as Ref. [31], we reproduce a similar distribution of fitting factors. Unlike previous purely Monte Carlo studies, however, our analytic approach allows us to quantitatively predict precisely which systems are not

\[^1\text{Aligned spin means that the spins of the compact objects are aligned with the orbital angular momentum. In this case there is no precession.}\]

\[^2\text{The full effects of precession are of course captured in full time-domain calculations of orbit dynamics and precession. These direct simulations, however, are presently too slow to be used in a search. Additionally, no one has constructed a complete template bank (a discrete set of reference signals) that adequately but minimally covers all possible signal options.}\]

\[^3\text{For example, the two-detector LIGO network is nearly aligned and approximately sensitive to one polarization at a time. In a subsequent paper we will address explicitly how to rescale our results to the two-detector LIGO network.}\]
well fit with nonprecessing templates. The performance of a nonprecessing search on BH-NS systems with any mass and spin distribution can be easily predicted using our amplitude and mismatch predictions, and the simple predictions for the parameters that cause bad matches point the way toward improved searches.

In Sec. II we demonstrate that BH-NS binaries seen by gravitational-wave detectors will often evolve on a constant precession cone. In Sec. III we parameterize the ways in which the binary’s precession cone can be oriented relative to a single detector and its line of sight to the source. We find that there are three distinct regions in this configuration space. In Sec. IV we review the leading-order gravitational-wave emission from a precessing binary, decomposing it into secular and modulated factors. We show how the gravitational-wave signal from each region has a distinctive secular dependence. Finally, in Sec. V we average the amplitude over the precession cone, relating the mean power seen along the line of sight to the power expected from an optimally oriented source. Additionally, we argue that nonprecessing signal templates necessarily cannot reproduce oscillations in the precessing signal model. Using a similar average and assuming a generic signal model reproduces the secular phase, we find an expression for the mismatch between nonprecessing and precessing signals.

II. ORBIT DYNAMICS AND THE CONSTANT PRECESSION CONE LIMIT

We consider a binary of two compact objects with masses \(m_1\) and \(m_2\), with \(m_1 \geq m_2\), and intrinsic spins \(\vec{S}_1\) and \(\vec{S}_2\). From the coordinate separation \(\vec{r}\) and the velocity \(\vec{v} = \partial_t \vec{r}\), we can define the coordinate Newtonian angular momentum \(\vec{L} = \mu \vec{r} \times \vec{v}\), where \(\mu = \frac{m_1 m_2}{m_1 + m_2}\) is the reduced mass.

For generic binaries, the orbit and spins evolve according to complicated position-, spin-, and velocity-dependent expressions [32,38,39]. Averaging these PN spin evolution equations over a few orbital periods leads to adiabatic expressions for the evolution of spin and orbital frequency (see, e.g., Ref. [35] (henceforth ACST), Schnittman [39]):

\[
\frac{\partial_t \vec{L}}{\partial_t \vec{S}_1} = \hat{\Omega}_L \times \vec{L},
\]

\[
\frac{\partial_t \vec{L}}{\partial_t \vec{S}_1} = \hat{\Omega}_{\vec{S}_1} \times \vec{S}_1, \quad \frac{\partial_t \vec{L}}{\partial_t \vec{S}_2} = \hat{\Omega}_{\vec{S}_2} \times \vec{S}_2,
\]

\[
\hat{\Omega}_L = \frac{1}{\vec{r}^3} \left[ \left( 2 + \frac{3m_2}{2m_1} \right) \vec{S}_1 + \left( 2 + \frac{3m_1}{2m_2} \right) \vec{S}_2 - \frac{3}{2|L|} \left( \vec{S}_2 \cdot \vec{L} \right) \vec{S}_1 + \left( \vec{S}_1 \cdot \vec{L} \right) \vec{S}_2 \right],
\]

\[
\hat{\Omega}_{\vec{S}_1} = \frac{1}{\vec{r}^3} \left[ \left( 2 + \frac{3m_2}{2m_1} \right) \vec{L} + \frac{3}{2|L|} \vec{S}_2 - \frac{3}{2} \vec{S}_2 \cdot \vec{L} \right],
\]

\[
\hat{\Omega}_{\vec{S}_2} = \frac{1}{\vec{r}^3} \left[ \left( 2 + \frac{3m_1}{2m_2} \right) \vec{L} + \frac{3}{2|L|} \vec{S}_1 - \frac{3}{2} \vec{S}_1 \cdot \vec{L} \right].
\]

In this expression we have omitted the quadrupole-monopole term described in Ref. [39] to more clearly correspond with the expressions from ACST on which we rely. We have included the spin-spin terms (containing both \(\vec{S}_1\) and \(\vec{S}_2\)) for reference but we will soon assume that only one body is spinning. These evolution equations cause \(\vec{S}_1\) and \(\vec{S}_2\) to precess but leave their magnitude constant. The direction \(\vec{L}\) of the orbital angular momentum also precesses and gravitational-wave emission causes the length of \(\vec{L}\) to shrink as the binary evolves.

As described in ACST, when either one mass is non-spinning (e.g., \(\vec{S}_2 = 0\)), the component masses are comparable \((m_1 \approx m_2)\), or the smaller mass has a miniscule mass and necessarily spin \((m_1 > m_2)\), these expressions reduce to effectively single-spin evolution, meaning equations of motion are equivalent to the dynamics of \(\vec{L}\) and a single (effective) spin. For single-spin binaries, spin-orbit evolution can occur in effectively two phases: (i) rare transitional precession when \(\vec{J} = \vec{L} + \vec{S} \approx 0\), the relative change in \(\vec{J}\) is large, and \(\vec{J}\) can change direction; and (ii) simple precession, when the vectors \(\vec{L}\) and \(\vec{S}\) precess roughly steadily around \(\vec{J}\).

Single-spin evolution is particularly appropriate for BH-NS binaries. Neutron stars likely do not spin rapidly \((\vec{S}_2 = 0)\)—observations suggest spin periods of no less than a few milliseconds [40]. Observations and theoretical considerations constrain plausible NS masses to 1–3\(M_\odot\), ensuring the second object’s minimal spin has little impact on the orbit about an a priori higher-mass companion. Albeit with less accuracy, BH-BH systems also often approximately satisfy the single-spin condition, as binaries that are either comparable mass or dominated by a single spinning body occupy most of the \(m_1, m_2, \vec{S}_1, \vec{S}_2\) parameter space; see, e.g., the discussion in Ref. [18].

A. Simple precession

For the circular orbits expected in astrophysical scenarios, the spin evolution equations usually imply simple precession: the orbital and spin angular momenta precess about the total angular momentum, which is fixed, except for negligible precession of its own about its average direction (ACST). Assuming \(\vec{S}_2 = 0\), the system evolves with \(\kappa = \vec{L} \cdot \vec{S}_1\) and \(|\vec{S}_1|\) both constant. At early times, the total angular momentum \(\vec{J}\) is dominated by and closely aligned with \(\vec{L}\); as radiation carries away orbital angular momentum, eventually \(\vec{J}\) is dominated by and closely aligned with \(\vec{S}\). As the direction of the total angular momentum is nearly conserved, this process involves substantial changes in the spin and orbital angular momentum directions. Following ACST, we will employ the ratio of \(\vec{S}_1\) to the Newtonian angular momentum \(\vec{L} = \mu \vec{r} \times \vec{v}\) as a parameter:
At the level of accuracy of interest here, the opening angle \( \beta \) of the precession cone (denoted \( \lambda_e \) in ACST) can be expressed trigonometrically as

\[
\beta(t) = \arccos \hat{J} \cdot \hat{L} = \arccos \frac{1 + \kappa \gamma}{\sqrt{1 + 2\kappa \gamma + \gamma^2}}.
\]

Using this parameter, the opening angle \( \beta \) of the precession cone is aligned\(^4\) and for a spin-orbit aligned binary (\( \gamma = 0 \)) all three of the spin, orbit, and total angular momenta are aligned (\( \beta = 0 \)). At the level of accuracy of interest here,\(^4\) the opening angle \( \beta(f) \) at a given gravitational frequency \( f \) can be estimated by the above expression, combined with the leading-order Newtonian expression \( r(f) = M(M\pi f)^{-2/3} \):

\[
\gamma \approx \frac{m_1 (m_1/M)^2}{\eta} (M\pi f)^{1/3} = 2.5\gamma_1 (m_1/10m_2) \left( \frac{fM}{100 \text{ Hz} \times 10M_\odot} \right)^{1/3}.
\]

Figure 1 shows an example of \( \beta(f) \) deduced from this expression.

During simple precession over longer time scales, the width of the precession cone increases on the gravitational-radiation time scale \( \tau_{gw} \approx \left[ r^4/(\eta M^3) \right] (5/64) \). During this slow increase, the orbital angular momentum traces out an ever-widening spiral at the precession frequency:

\[
\dot{L}_\perp = \left( 2 + \frac{3m_2}{2m_1} \right) \frac{j}{r^3} \times L,
\]

\[
\hat{\Omega}_p = \left( 2 + \frac{3m_2}{2m_1} \right) \frac{j}{r^3},
\]

\[
|\Omega_p| = \left( 2 + \frac{3m_2}{2m_1} \right) \left( \frac{\mu}{M} \right) \left( M\pi f \right)^{5/3} \frac{|\hat{L}|}{|\hat{S}|} \quad |\hat{L}| \gg |\hat{S}|,
\]

where we have replaced \( r \) by the leading-order PN expression \( v^2 = (M/r) = (M\pi f)^{-2/3} \) and \( L_N = \mu M(M\pi f)^{-1/3} \) ACST provides an explicit, algebraic solution for the spins as a function of time [their Eqs. (59–63)].

\(^4\)As described at greater length in a subsequent publication, our constant precession cone approximation is designed to be accurate to or order several percent in power and mismatch. Quantitative comparisons of our approximation to numerical simulations will be provided in that publication.

B. Regions of parameter space I: L, S, dominated or intermediate

Single-spin binaries can be loosely subdivided into rare transitional precession and ubiquitous simple precession (ACST). In band, simple precessing binaries can be either \( \hat{L} \) or \( \hat{S} \) dominated. A spin dominated binary can have an arbitrary opening angle. An \( \hat{L} \) dominated binary, by contrast, has a precession cone opening angle necessarily smaller than \( \pi/2 \), and bounded above by

\[
\beta_{\text{max}} = \sin^{-1} \gamma.
\]

In the neighborhood of this extreme misalignment, at \( \kappa = -\gamma \), the opening angle is nearly stationary with spin-orbit misalignment (i.e., \( d \cos \beta / d\kappa \approx 0 \)) (see, e.g., Fig. 2). In short, a distribution of \( \hat{L} \) dominated binaries has two choices for spin-orbit misalignment (i.e., two values of \( \kappa \)) consistent with each realized opening angle. Additionally, because of the local maximum in \( \beta \) as a function of \( \kappa \), a randomly oriented distribution of spins will have opening angles \( \beta \) that cluster near that maximum (i.e., \( \beta \approx \beta_{\text{max}} \)). To illustrate which regions are \( \hat{L} \) and \( \hat{S} \) dominated, Fig. 3 shows contours of constant \( \gamma \), assuming \( m_2 = 1.4M_\odot \).

C. Regions of parameter space II: Steady precession and geometry

Unless transitional precession happens in band, ground-based gravitational-wave detectors are sensitive to emission from a relatively well-defined epoch: the precession cone has a relatively constant opening angle (Fig. 1).

\[
\text{FIG. 1. Constant precession cone approximation works: Opening angle } \beta(f) \text{ versus frequency for a } 10M_\odot + 1.4M_\odot \text{ binary with } \chi_1 = 1 \text{ and } \arccos \kappa = 0, \pi/10, \ldots \text{ (bottom curves) up to } \arccos \kappa \approx \pi \text{ (top, rapidly changing curve). We estimate } \beta(f) \text{ using Eqs. (3) and (4). This plot shows that except for highly misaligned binaries (arccos \kappa large), } \beta(f) \text{ is nearly constant, changing at most a fraction of a radian across the sensitive band of present and future detectors. In general, only a small subset of masses and highly misaligned spins are finely tuned enough to produce significant } \beta \text{ evolution in band.}
\]
Quantitatively, we define a reference frequency $f_{\text{peak}}$ corresponding to the frequency up to which half of the signal power has been accumulated. The specific reference frequency depends on the noise curve adopted. For this paper, we adopt the fiducial advanced LIGO noise curve with zero-detuned signal recycling; see Ref. [41]. This includes a low-power mode for which $f_{\text{peak}} \approx 40$ Hz and high-power mode for which $f_{\text{peak}} \approx 60$ Hz. However, all planned noise curves we have examined have a reference frequency in the neighborhood of which a constant precession cone is a good approximation. Henceforth the ratio $\gamma = |S|/|L|$ and opening angle $\beta$ between $\hat{L}$ and $\hat{J}$ will refer to quantities predicted by this frequency by the simple precession expressions [Eqs. (4) and (3)].

Second, not only is the precession cone nearly fixed, but as shown in Fig. 4 at least a few complete precession cycles occur between 20–100 Hz, where most of the signal to noise accumulates. For example, for an angular momentum dominated binary ($\gamma \ll 1$), the number of precession cycles for a single-spin binary can be approximated by the spin-independent expression

In the text we choose the reference frequency as the half-power point, where $\int f^{-3/2} S_0(f) df$ reaches half of its total value. Alternatively, the reference frequency can be set by maximizing $d\rho/d\ln f = 4f|h(f)|^2/S_0$, or even phenomenologically, in whatever manner is needed for numerically calculated amplitude and match to reproduce our expressions. For the noise curves considered in this paper, all approaches nearly agree.

For simplicity, we adopt the leading-order (Newtonian) expression for $r(f)$. Higher order corrections are small.

With a comparable but spin-dependent number for an $S$ dominated binary ($\gamma \gg 1$); see ACST Eqs. (45, 63) for a general solution. As indicated by Fig. 4, each precession cycle usually accumulates a comparable proportion of detectable power (i.e., each pair of peaks is a similar order of magnitude in area). More critically, the figure indicates that at least one and often several precession cycles contribute to the total signal to noise. With many precession cycles, a gravitational-wave detector should be relatively insensitive to the initial value of the precession phase.

---

**FIG. 2 (color online).** Precession opening angle versus spin-orbit misalignment: Relation between $\kappa = L \cdot S$ and $\beta = \cos^{-1} L \cdot J$ for $\gamma = |S|/|L| = 0.5, 0.6 \ldots 1.5$. Binaries that are angular momentum dominated ($\gamma < 1$) can have only a small range of precession cone opening angles, bounded by $\beta_{\text{max}} = \cos^{-1}\sqrt{1-\gamma^2}$. Binaries that are spin dominated ($\gamma > 1$) can have all possible precession cone opening angles. For extremely spin dominated binaries $\kappa = \cos \beta$.

**FIG. 3.** Angular momentum dominated versus spin dominated binaries: In terms of the mass and spin of the black hole, contours of the ratio $\gamma = |S|/|L|$ evaluated at 40 Hz. The bottom left region is angular momentum dominated ($|S| \gg |L|$); the top right region of large black hole mass and spin is strongly spin dominated ($|S| \gg |L|$). Contours show the ratio $|S|/|L| = \gamma = 1$ (thick curve), $\sin \pi/4 = 1/\sqrt{2}$, $\sin \pi/6 = 1/2$ and $\sin \pi/8$, evaluated with a 1.4$M_\odot$ NS companion, versus the black hole mass and spin parameters $m_{\text{BH}}, \chi_{\text{BH}}$. Above (below) the thick curve, BH-NS binaries’ total angular momenta are spin (orbit) dominated in band. If spin and orbital angular momenta are nearly anti-aligned, these binaries have undergone transitional precession at lower frequencies, typically not in band. Conversely, for orbital-angular momentum dominated binaries ($\gamma < 1$), transitional precession has not occurred in the past at lower frequencies and may, if antialigned and $\gamma \approx 1$, occur in band in the immediate future. Finally, below the bottom curve, BH-NS binaries’ waveforms are modulated little by precession in band.
For our purposes, then, the binary undergoes nearly steady simple precession in band. The instantaneous beam pattern of the binary is aligned with the instantaneous $^\mathbf{L}$, and is the same beam pattern as a nonspinning binary \[ 42\]. Along the axis aligned with $^\mathbf{C}6^\mathbf{L}$, the radiation is circularly polarized and in the orbital plane, the radiation is linearly polarized. Over a longer time scale, $^\mathbf{L}$ precesses around $^\mathbf{J}$, sweeping the beam pattern around the precession cone. Any given line of sight therefore can be characterized with its proximity to the orbital plane (an amplitude minimum and specific, linear polarization) and $^\mathbf{C}6^\mathbf{L}$ (an amplitude maximum and specific circular polarizations).

D. Constant precession cone coordinates

In steady precession the unit vector $^\mathbf{L}$ rotates regularly about $^\mathbf{J}$. In practice, however, we interpret the gravitational-wave strain relative to a frame associated with our line of sight $^\mathbf{C}0^\mathbf{n}$, where $^\mathbf{n}$ is the emission direction from the binary. To simplify calculations, we adopt a frame defined by this direction: $^\mathbf{C}0^\mathbf{z}$, along with two perpendicular directions $^\mathbf{C}0^\mathbf{x}$, $^\mathbf{C}0^\mathbf{y}$. Adopting an initial phase so the projection of $^\mathbf{L}$ into the plane of the sky (i.e., perpendicular to $^\mathbf{n}$) is along $^\mathbf{C}0^\mathbf{J}$, the unit vectors needed to describe the steady precession approximation are

\[
^\mathbf{J} = \sin \theta \left[ \cos \psi \hat{x} + \sin \psi \hat{y} \right] + \cos \theta \hat{n},
\]

\[
^\mathbf{p} = \frac{\hat{J} \times (\hat{J} \times \hat{n})}{|\hat{J} \times (\hat{J} \times \hat{n})|} = \cos \theta \left[ \cos \psi \hat{x} + \sin \psi \hat{y} \right] - \sin \theta \hat{n}.
\]

FIG. 4. Several precession cycles contribute comparably to the signal: Power ($\left| \tilde{h}_x \right|^2/S_h(f)$) versus frequency for a spinning binary viewed edge on the $^\mathbf{C}0^\mathbf{x}$ polarization, computed directly from a Fourier transform of the gravitational-wave signal. In this figure, the binary is a $10 + 1.4M_\odot$ BH-NS binary with $\chi_1 = 1$ and $\beta^* = \pi/3$ (solid line). Each pair of peaks corresponds to a single precession cycle. The signal is divided by the high-power zero-detune advanced LIGO noise power spectral density [41].

For our purposes, then, the binary undergoes nearly steady simple precession in band. The instantaneous beam pattern of the binary is aligned with the instantaneous $^\mathbf{L}$, and is the same beam pattern as a nonspinning binary \[ 42\]. Along the axis aligned with $^\mathbf{C}6^\mathbf{L}$, the radiation is circularly polarized and in the orbital plane, the radiation is linearly polarized. Over a longer time scale, $^\mathbf{L}$ precesses around $^\mathbf{J}$, sweeping the beam pattern around the precession cone. Any given line of sight therefore can be characterized with its proximity to the orbital plane (an amplitude minimum and specific, linear polarization) and $^\mathbf{C}6^\mathbf{L}$ (an amplitude maximum and specific circular polarizations).

D. Constant precession cone coordinates

In steady precession the unit vector $^\mathbf{L}$ rotates regularly about $^\mathbf{J}$. In practice, however, we interpret the gravitational-wave strain relative to a frame associated with our line of sight $^\mathbf{C}0^\mathbf{n}$, where $^\mathbf{n}$ is the emission direction from the binary. To simplify calculations, we adopt a frame defined by this direction: $^\mathbf{C}0^\mathbf{z}$, along with two perpendicular directions $^\mathbf{C}0^\mathbf{x}$, $^\mathbf{C}0^\mathbf{y}$. Adopting an initial phase so the projection of $^\mathbf{L}$ into the plane of the sky (i.e., perpendicular to $^\mathbf{n}$) is along $^\mathbf{C}0^\mathbf{J}$, the unit vectors needed to describe the steady precession approximation are

\[
^\mathbf{J} = \sin \theta \left[ \cos \psi \hat{x} + \sin \psi \hat{y} \right] + \cos \theta \hat{n},
\]

\[
^\mathbf{p} = \frac{\hat{J} \times (\hat{J} \times \hat{n})}{|\hat{J} \times (\hat{J} \times \hat{n})|} = \cos \theta \left[ \cos \psi \hat{x} + \sin \psi \hat{y} \right] - \sin \theta \hat{n}.
\]
Here $\psi_J$ is the orientation of $\hat{J}$ projected into the plane of the sky and $\theta_J$ is the angle between $J$ and $\hat{n}$; see Fig. 5. In terms of these vectors, the precession of the orbital angular momentum about $\hat{J}$ can be described as

$$\dot{\hat{L}} = \cos \beta \hat{J} + \sin \beta R_J(\alpha) \hat{\rho},$$

(10c)

where $R_J(\alpha)$ is a rotation operator about $J$ and $\alpha = \int \Omega_J dt$ is the precession phase of $\hat{L}$ around that axis [35]. The gravitational-wave strain recovered by a detector depends on the orientation of $\hat{L}$ relative to the radiation frame. In terms of the coordinates above, the inner products needed are

$$\hat{L} \cdot \hat{n} = \cos \beta \cos \theta_J - \sin \beta \sin \theta_J \cos \alpha,$$

(10d)

$$\hat{L} \cdot \hat{x} + i \hat{L} \cdot \hat{y} = e^{i \psi_J} / [\sin \beta (\cos \alpha \cos \theta_J + i \sin \alpha) + \cos \beta \sin \theta_J],$$

(10e)

$$= e^{i \psi_L} \sqrt{1 - (\hat{L} \cdot \hat{n})^2},$$

(10f)

where $\psi_L$ is shorthand for the instantaneous orientation of $\hat{L}$ on the plane of the sky.

For convenience and without loss of generality, in what follows we will assume the binary is directly overhead a single interferometer, with arms along $\hat{x}$ and $\hat{y}$. For this orientation, the detector response functions are $F_+ = \cos^2 \psi_J$, $F_\times = \sin^2 \psi_J$. If the source is not directly overhead, the single-detector response functions

$$F_+ = \frac{1}{2} (1 + \cos^2 \theta) \cos 2 \phi - \cos \theta \sin 2 \phi \sin 2 \psi,$$

(11a)

$$F_\times = \cos \theta \sin 2 \phi \cos 2 \psi + \frac{1}{2} (1 + \cos^2 \theta) \cos 2 \phi \sin 2 \psi,$$

(11b)

can be rewritten as an overall scaling and a polarization shift

$$F_+ = F_0 \cos 2(\psi + \psi_0),$$

(11c)

$$F_\times = F_0 \sin 2(\psi + \psi_0),$$

(11d)

with

$$F_0 = \sqrt{(1 + \cos^2 \theta)/2} \cos^2 2 \phi + \cos^2 \theta \sin^2 2 \phi$$

(11e)

$$\tan 2 \psi_0 = \frac{\cos \theta}{(1 + \cos^2 \theta)/2} \tan 2 \phi.$$  

(11f)

III. CRITICAL VIEWING ORIENTATIONS AND DOMAINS

The instantaneous emission pattern of gravitational radiation is aligned with the instantaneous orbital angular momentum $\hat{L}$ and is the same as the beam pattern of a nonspinning binary i.e., an $l = m = 2$ quadrupolar configuration. The radiation is circularly polarized along $L$ and $-L$ and linearly polarized in the plane perpendicular to $L$. In particular, when the orbital angular momentum is instantaneously perpendicular to the line of sight, one (linear) polarization of the gravitational-wave signal is instantaneously zero. The condition that one polarization be zero at some instant defines a two-dimensional surface in the three-dimensional space ($\theta_J$, $\psi_J$, $\beta$) of all possible precession cone geometries. As we show below, this surface decomposes the three-dimensional space into three distinct regions, corresponding to different ways the orbital plane crosses the line of sight or, equivalently, different

![FIG. 6 (color online). Three regions have three types of precession cones: Shown is the precession cone for three fiducial binaries, characterized by the angles $(\theta_J, \beta, \psi_J) = (\pi/4, \pi/6, 0), (\pi/2, \pi/4, \pi/4),$ and $(\pi/2, \pi/3, 0)$. Each figure shows the precession-induced path of $\hat{L}(t)$ (colored circles), the total angular momentum direction (arrow), and an example of an instantaneous $L$ direction (arrow). As these three examples demonstrate, each region corresponds to a different way the precession cone wraps around the two dotted lines. These two lines correspond to orientations of $\hat{L}$ such that the detector would instantaneously see exactly zero amplitude. We will henceforth denote them as "null lines." These three precession cones are representative examples of the three regions discussed in the text: R1 (left panel), R2 (middle panel), and R3 (right panel)](064020-7)
ways the orbital angular momentum wraps around two null lines.

The detector is not sensitive to (leading-order) gravitational radiation emitted from the binary when the orbital angular momentum simultaneously satisfies the following two conditions:

\[ 0 = \hat{L} \cdot \hat{r} = 0, \]  
\[ 0 = (\hat{L} \cdot \hat{x})^2 - (\hat{L} \cdot \hat{y})^2. \]

Solutions to these expressions exist if and only if the angle between \( \hat{J} \) and one of the four critical directions indicated in Fig. 6 is equal to the angle \( \beta \) between \( \hat{J} \) and \( \hat{L} \), or equivalently if the following expression is zero:

\[ d_{\text{null}} = (\hat{J} \cdot v_1 - \cos \beta)(\hat{J} \cdot v_1 + \cos \beta) \]
\[ + \cos \beta (\hat{J} \cdot v_2 - \cos \beta)(\hat{J} \cdot v_2 + \cos \beta) \]  
\[ = [(\hat{J} \cdot v_1)^2 - \cos^2 \beta][(\hat{J} \cdot v_2)^2 - \cos^2 \beta], \]  
\[ \text{where} \quad v_1 = (\hat{x} + \hat{y})/\sqrt{2} \quad \text{and} \quad v_2 = (\hat{x} - \hat{y})/\sqrt{2}. \]

Substituting in the coordinate form for \( \hat{J} \) given above and solving \( d_{\text{null}} = 0 \) for \( \cos^2 \psi \) leads to an expression for the boundary polarization angle \( \psi_{J, \text{crit}} \) between different regions:

\[ \cos^2(2\psi_{J, \text{crit}}) = \frac{4 \cos^2 \beta (\cos^2 \beta - 1)}{\sin^2 \theta} \]
\[ = - \frac{(1 + \cos 2\beta)(\cos 2\beta + \cos 2\theta)}{\sin^2 \theta}. \]

These configurations defined above divide the space of orientations \( (\theta_j, \beta, \psi_j) \) into five regions, henceforth denoted \( R1_\pm, R2_\pm, \) and \( R3 \) (Fig. 7). As our notation suggests, using symmetry we can relate two pairs of regions by reflection symmetry \( \beta \rightarrow -\beta \). The region \( R1 \) (the union of \( R1_+ \) and \( R1_- \)) corresponds to all configurations such that the orbital angular momentum does not wind around either null line. It includes all points where the orbital plane does not cross the line of sight, plus those connected orientations that never have a null in the waveform amplitude. Because of a coordinate degeneracy in Fig. 7, the region shown corresponding to \( R1 \) consists of two disjoint mirror-image copies \( R1_\pm \), related by \( \beta \rightarrow \pi - \beta \). These two regions include the special cases of spins aligned or antialigned with the total angular momentum, viewed along or opposite to the total angular momentum. Conversely, the region \( R3 \) corresponds to binaries and viewing geometries so \( L \) winds around both null lines. The region \( R3 \) includes the special case of a \textit{precession disk} \((\beta = \pi/2)\), viewed favorably edge on \((\theta_j = \pi/2, \psi_j = 0)\), plus those connected orientations free from amplitude zeros. The two regions \( R2_\pm \) correspond to the ways \( L \) can wind around one or the other null line. At every polarization except \( \psi_j = 0 \), the regions \( R1 \) and \( R3 \) are separated by \( R2 \). For \( \psi_j = 0 \), the three regions overlap at the zeros of

**FIG. 7** (color online). Region divisions in coordinate form: The three ways the binary’s orbital angular momentum can wind around the two null lines are separated by cases where the cone is tangent to one or the other axis. In this figure we express this dividing surface using explicit coordinates for the 3d configuration space: \( z = \cos^2 \psi_j, \ x = \cos 2\theta_j, \ y = \cos 2\beta \). Points on this surface are simultaneous solutions to Eq. (12), as calculated by Eq. (15). In this figure, the R1 region is the largest, farthest from the viewer; the region R3 is the region above the surface, closest to the viewer; and the region R2 is below the surface.

\[ \cos 2\theta_j + 2 \cos 2\beta + 1 = 2[\sin^2 \theta + \cos 2\beta]. \]

**IV. WAVEFORMS IN CONSTANT PRECESSION CONE LIMIT**

In this section we review how precession modulates the amplitude and phase of the binary’s gravitational-wave signal. We express precession-induced amplitude and phase modulations in terms of a complex factor \( z \). We show the gravitational-wave phase has both oscillating and secularly increasing contributions from precession. The secular effect arises as a fraction of the precession phase is imprinted on the signal. We demonstrate that each of the previously identified regions corresponds to a different amount of secular precession contribution. To leading order, gravitational-wave detection with nonprecessing templates works by matching a signal with similar \textit{phase} evolution. In this sense, gravitational-wave signals from each of the three regions are phenomenologically similar (and can be phenomenologically distinguished from one another), as each region has a characteristic secular phase evolution change from precession.

Explicit expressions for the leading-order gravitational waveforms produced by instantaneously stationary orbits are available in the literature; see, e.g., Eqs. (31)–(37) and Fig. 1 from Buonanno et al. [20]. Additionally, though these expressions can be evaluated in any coordinate system (see, e.g., Fig. 1 in Buonanno et al. [20]), we adopt a specific coordinate system aligned with the total angular
momentum. [These coordinates are different from the frame adopted in Eq. (10).] In our coordinate system, the expressions provided in Buonanno et al. [20] correspond to the expressions below, with their $\iota$ corresponding to our $\beta$ and their $\Theta$ corresponding to our $\theta$. In these expressions,

\[
h \propto (C_+ F_+ + C_ X F_X) \cos(2\phi_{\text{orb}} - 2\alpha \cos \beta) + (S_+ F_+ + S_X F_X) \sin(2\phi_{\text{orb}} - 2\alpha \cos \beta)
\]

Practically speaking, the phase increases and oscillates with time. The gravitational-wave phase is decomposed into three parts:

- (a) orbital modulation $\phi_{\text{orb}}$,
- (b) precession-induced secular increase in phase imposed by geometrical effects associated with precession ($W\alpha$), and
- (c) residual modulations in phase caused by precession ($\delta \phi_{\text{prec}}$).

Both the secular evolution factor $W$ and modulations depend on the line of sight; see Fig. 8 for three examples.

The secular phase evolution $W$ is particularly simple. For example, for binaries and viewing orientations where the orbital plane never crosses the line of sight, corresponding to a single helicity being present along the line of sight, the secular phase must accumulate steadily in proportion to this helicity. Using the special case $\theta = 0$, $\pi$ to determine suitable coefficients, one can show that

\[
W = (\text{sign}(\cos \beta) - \cos \beta).
\]

More generally, the secular phase factor $2W$ is $-2\cos \beta$ plus an integer, related to the number of times the complex number $z$ winds around the point $z = 0$ in a precession cycle (i.e., versus $\alpha$):

\[
W = \frac{1}{2} n_{\text{wind}} - \cos \beta = -\cos \beta + \frac{1}{4\pi i} \int \frac{dz}{z}.
\]

where this integral follows a contour in $z$ corresponding to $\alpha$ evolving from 0 to $2\pi$ (i.e., one precession cycle).

Figure 9 show examples of different trajectories for the complex amplitude $z(t)$. Depending on how the angular momentum winds around the two “null lines” (Fig. 6), the complex number $z$ derived from the angular momentum and the detector orientation can wind around the origin (the point corresponding to $\hat{L}$ along those null lines). This integral can be explicitly evaluated, for example, by substituting $u = e^{i\alpha}$ and performing a contour integral. Since by construction the complex number $z$ is exactly zero at

FIG. 8 (color online). Phase evolution versus time: For three selected viewing geometries of a single binary with $\beta = 60^\circ$, a plot of $\Phi - \Phi_{\text{BCV}}(t) = \text{arg}(z)$ versus $\alpha$, the precession phase. This plot shows how much of the precession phase is accumulated in the gravitational-wave signal due to precession [Eq. (21)]. These three phase evolutions are generated from Eqs. (17). The dotted line corresponds to $W\alpha$, where $W$ corresponds to the rate of secular phase increase appropriate to that line of sight. The three viewing geometries lie in the three regions R1, R2, R3 described in the text.
some point on its cycle if and only if Eq. (12) holds, the connected subsets of R1, R2, and R3 are also regions of constant winding number \( n_{\text{wind}} \). Keeping in mind the regions have different connected subsets depending on the sign of \( \cos \beta \), we evaluate \( W \) and find

\[
W \equiv -\cos \beta + \begin{cases} 
\text{sign}(\cos \beta) & \text{R1} \\
\frac{1}{2} \text{sign}(\cos \beta) & \text{R2} \\
0 & \text{R3}
\end{cases}
\]  (24)

ACST find an approximately comparable result (their Eq. (65); see also Ref. [37]) by integrating an ordinary differential equation for the phase perturbation due to precession. That expression does not include the region R2 or correctly identify the conditions that cause transition from one secular phase to another.

The complex amplitude \( z(t) \) also encodes the way that the gravitational-wave phase and amplitude “oscillate” about their representative values. Binaries whose angular momenta are aligned with their orbit do not precess, so they do not accumulate secular precession phase (\( W = 0 \), as \( z \propto e^{i2\pi} \)) and their phase does not oscillate. As is apparent from the \( z(t) \) trajectories in Fig. 9, any oscillations in amplitude and phase are more extreme for trajectories passing closer to \( z \approx 0 \). These extreme oscillations cannot be well fit by a nonprecessing template. We will show below that the best fitting factor between a precessing signal and a nonprecessing template family correlates directly with the amount of phase and amplitude oscillation that a signal exhibits.

By way of example, Fig. 8 shows how precession introduces additional secular and oscillating contributions to the gravitational-wave phase of the same binary, seen along different lines of sight. The three curves in this figure show \( \arg(z) \) versus \( \alpha \), as extracted from \( z(\alpha) \) (Fig. 9). We can clearly see the distinct secular phase trajectories, corresponding to each of the three ways \( \tilde{L} \) can wind around the “null lines” [equivalently, how \( z(t) \) can wind around the origin].

V. AVERAGING AMPLITUDE AND MISMATCH WITH THE PRECESSION CONE

In this section we estimate the response of gravitational-wave detectors and nonprecessing data analysis strategies to a precessing signal. Using a separation of time scales argument, we show that precession-induced modulations decouple from the orbital phase, allowing key expressions like the signal amplitude and mismatch against proposed signal templates to be computed by an average over the precession cone. We apply this idea to compute how precession modifies two quantities: the signal strength and the mismatch of a nonprecessing template with a precessing signal. Combined, these expressions tell us the relative signal strength a data analysis pipeline would recover from a precessing binary, given we know how well it performs for a nonprecessing counterpart (i.e., one with similar masses but aligned spins).

The signal-to-noise ratio for the detection of an exact template waveform \( h_e \) using an optimal filter constructed from a model waveform \( h_m \) used as a template is given by

\[
\rho_m = \langle h_e | h_m \rangle = \frac{\langle h_e | h_m \rangle}{(h_m | h_m)^{1/2}}.
\]  (25)

where the noise-weighted inner product \( (h_e | h_m) \) is given by

\[
\langle h_e | h_m \rangle = 2 \int_{-\infty}^{\infty} df \frac{\tilde{h}_e(f)\tilde{h}_m^*(f)}{S_n(|f|)}.
\]  (26)

Here \( S_n(|f|) \) is the one-sided power spectral density of the detector strain noise \( n(t) \), defined by

\[
\langle \hat{n}(f)\hat{n}^*(f') \rangle = \frac{1}{2} \delta(f - f')S_n(|f|).
\]  (27)

and \( \tilde{h}(f) \) is the frequency-domain representation of the waveform, given by

\[
\tilde{h}(f) = \int_{-\infty}^{\infty} h(t)e^{-2\pi if't}dt.
\]  (28)
If we know the exact waveform, the strength of the signal is given by \( \rho^2 = \langle h_0 | h \rangle \). However, if there is an error in the waveform model \( h_m \), then the signal-to-noise ratio is reduced by a factor
\[
\rho_m = M \rho, \tag{29}
\]
where \( 0 \leq M \leq 1 \) is the match of the model signal. The model waveform \( h_m = h_m(\tilde{\lambda}) \) is a function of the model’s intrinsic parameters \( \tilde{\lambda} \) (e.g., masses, spins, etc.) and extrinsic parameters \( \lambda_e \) (e.g., time of arrival, coalescence phase, sky location, etc.). The model waveform having the same physical parameters as the exact waveform \( h_m \) might not have the highest match, and so we define the fitting factor \( F \) as
\[
F = \max_{\tilde{\lambda}, \lambda_e} \langle h_0 | h_m(\tilde{\lambda}, \lambda_e) \rangle. \tag{30}
\]
For the best-fit parameters, the signal-to-noise ratio will be reduced by a factor of \( \rho_m = F \rho \).

In this section we use the constant precession cone approximation to derive closed-form expressions for the fitting factor \( F \) and the geometrical factors in the signal amplitude \( \rho^2 \). Formally, our approximation arises through separation of time scales. At each instant, the gravitational-wave emission is instantaneously quadrupolar. Expanding in powers of \( \Omega p / \pi f \), the time-domain amplitude modulation \( A(t) \) implied by the beam pattern translates directly to frequency-domain modulation \( A(t f) \) [ACST Eqs. (36) and (37)]; see, e.g., Fig. 4. Each frequency identifies an orientation of the angular momentum vector \( \hat{L}(f) \) and thus precession phase \( \alpha \). So long as a few precession cycles dominate peak emission, a single (effectively “constant”) precession cone dominates as well. Adopting this precession cone as fiducial, we can transform the inner products involving \( A(t f) = A_p(f) B(\hat{L}(t)) \) into inner products involving the “slow” degrees of freedom [i.e., just \( A(f) \)] and averages over the “fast” (precession) degrees of freedom \( B(\hat{L}) \). The averages over slow degrees of freedom do not explicitly depend on precession geometry, detector noise, or component masses. The expression factors. We therefore arrive at expressions for \( \rho^2 \) and \( F \) in terms of averages. As these averages encode all orientation-dependent effects, we emphasize the averages below, keeping in mind that their prefactors (if needed) can be easily computed once and for all, using a face-on binary.

### A. Averaged amplitude

The precession of the beam across the line of sight modulates the amplitude seen at a single detector, in both \( sin \) and \( cos \) quadratures. We estimate the signal power by adding each quadrature’s contribution independently, including the prefactor implied by the orientation of \( \hat{L} \) relative to the line of sight and detector. We then average the resulting expression over the entire precession cone. Compared to the geometrical factor for an optimally oriented nonprecessing source, the amplitude \( \rho^2 \) is smaller by a factor \( s^2 \):

\[
s^2 = s^2(\theta_j, \beta, \psi_j) = \left\{ \frac{(1 + (\hat{L} \cdot n)^2)}{4} \right\} \cos^22\psi_L(t) + (\hat{L} \cdot n) \sin^22\psi_L(t) \tag{31}
\]

\[
= \left\{ \frac{(1 + (\hat{L} \cdot n)^2)}{4} - (1 - (\hat{L} \cdot n)^2) \right\} \sin^22\psi_L(t)
\]

\[
= \left\{ \frac{(1 + (\hat{L} \cdot n)^2)}{4} - ((\hat{L} \cdot \hat{\chi})^2(\hat{L} \cdot \hat{\chi})) \right\}
\]

\[
= \frac{1}{1024} \left[ (c_p(x - 1)^2 + x^2)(35y^2 + 10y - 13) + 2x(5y^2 + 166y + 53) - 13y^2 + 106y + 451 \right]. \tag{32}
\]

where \( x = \cos2\theta_j, y = \cos2\beta, \) and \( c_p = \cos2\psi_j \). Note that all polarization dependence enters through a term \( \times c_p(1 - x)^2 + x^2 \); the average amplitude is almost polarization independent near \( \theta_j \approx 0 \).

Figure 10 shows how the relative amplitude of a BH-NS binary seen directly overhead a single detector should change, versus the purely geometrical orientation parameters \( \theta, \beta, \psi_j \) describing the constant precession cone.

### B. Averaging and fitting factor

The phase evolution is more subtle. As simple precession parallel-transport the orbit along a precessing path, the gravitational-wave phase \( \phi_{wave} \) of the single polarization to which our detector is sensitive oscillates about a combination of the orbital phase and a secularly accumulating proportion of the precession phase \( \alpha \):

\[
2\phi_{wave} = 2\phi_{orb} + 2\delta\phi_{prec}(\alpha) + 2\omega\alpha, \tag{33}
\]

as described above. Finally, the spin also influences the accumulation of orbital phase \( \phi_{orb} \); the projection of \( \vec{S}_i \) along \( \hat{L} \) produces a “gravitomagnetic repulsion,” changing the orbital evolution \( \phi_{orb} \) by slowing the rate of increase in frequency; see, e.g., Eq. (6) in Ref. [19].

For detectors like LIGO, which are sensitive to an epoch where the binary’s opening angle is nearly constant, the secular phase changes \( \phi_{orb} \) and \( \omega \alpha \) can be well fit by a sufficiently generic nonprecessing waveform.\(^7\) For

\(^7\)Roughly speaking this ansatz requires a large enough binary model space and small enough time range that the equation \( \phi_{orb}(\lambda, f) + W(\lambda)\alpha(f) \approx \phi_{orb}(\lambda', f) \) can be solved for one single set of parameters \( \lambda' \), for all \( f \) in band, and for each \( \lambda \). Empirically, this ansatz works well, even when the nonprecessing templates have no spin. To be concrete, we performed Monte Carlo studies described in Fig. 13 using a nonspinning template bank. So long as the template bank allowed the mass ratio parameter \( \eta \) to be greater than 1/\( \lambda \), all aligned spins could be well fit in the mass and mass ratio range of interest. Moreover, by explicitly constructing a waveform without geometrically induced modulations, we have confirmed a good fit between the secular evolution and nonprecessing signals.
example, the secular phase evolution of many precessing waveforms can be well fit by a nonprecessing waveform with different chirp mass and mass ratio ($M_c, \eta$). On the other hand, amplitude and phase oscillations in $A(t)$ and $\delta\phi_{\text{prec}}$ cannot be fit with nonprecessing templates.

Using the ansatz that the best nonprecessing template $h_m$ will perfectly reproduce the secular phase, the time-averaged overlap between the spinning waveform $h_c$ and the best nonspinning template must be proportional to the amplitude $\rho_{ns}$ of a nonspinning binary of comparable masses.

This expression reduces to a simple contour integral:

$$s F = \int \frac{dt}{T} (h_c(t)|h_m(t)),$$

where $s$ is the average amplitude from Eq. (31) and where the average is over a single precession cycle of $T$ in $h_c$, and where $h_m$ is the best-fitting nonspinning template to the entire cycle. Replacing a time average by an average over the precession phase $\alpha$ and the true signal $h_c(t)$ with the nonspinning template times the amplitude and (Fourier domain) precession phase terms $A$ and $\delta\phi$ described above, this expression reduces to an average of the oscillating amplitude and phase over the cycle:

$$s F = \max_{\phi_0} \int A \cos(2\delta\phi + \phi_0) d\alpha/(2\pi).$$

This expression reduces to a simple contour integral:

$$s F_c = \int \frac{d\alpha}{2\pi} (\bar{z}/Z + (\bar{z}/Z)^*) d\alpha,$$

$$s F_s = \int \frac{d\alpha}{2\pi} (\bar{z}/Z - (\bar{z}/Z)^*) d\alpha,$$

where $Z(\alpha) = e^{i2W\alpha}$, and $Z$ is the complex representation of the waveform amplitude and phase given in Eq. (20), while dividing by $Z$ is equivalent to subtracting the secular phase. Using the complex variable $u = e^{i\alpha}$ to represent $Z = u^{2W} = u^{\theta_{\text{total}}}$ and the sinusoids in $C_{+\times}$ and $S_{+\times}$ analytically via

$$(2\delta\phi)^2 + (\delta A/A)^2 = \frac{1}{2}[(2\delta\phi)^2 + (\delta A/A)^2].$$

This expression can be rederived directly from the original integral. In particular, the amplitude and phase modulations introduced by precession inevitably diminish the ability of a nonprecessing template to match them, by an amount proportional to the standard deviation of oscillations in time and phase about the reference model.

Oscillations in phase and amplitude are most extreme for binary geometries near the boundaries between regions. A nonprecessing signal should be maximally unable to match the large phase and amplitude variations near this surface. For example, a signal on the surface has different epochs, separated by zeros of the (complex) amplitude. A nonprecessing signal can coherently reproduce the phase trend in one portion of the signal or the other, but not both.

C. Constant Precession Cone

In the limit of a constant precession cone, the integral can be performed analytically. Replacing a time average by an average over the precession phase $\alpha$ and the true signal $h(\theta)$ with the nonspinning template times the amplitude and (Fourier domain) precession phase terms $A$ and $\delta\phi$ described above, the angle-averaged expression reduces to

$$F \approx 1 - \frac{1}{2}[(2\delta\phi)^2 + (\delta A/A)^2].$$

We will provide a closed-form expression in the next section. However, to understand that result, it is helpful to think directly in terms of this integral. For example, in the limit of small amplitude and phase modulations occurring periodically on the precession cone, a nonprecessing template model should fit them to no better than

FIG. 10 (color online). Amplitude ratio model: For spinning precessing binaries, the function $s(\theta_f, \beta, \psi_f = 0)$ describing the average amplitude along a given line of sight, assuming a steadily precessing binary with precession cone opening angle $\beta$. The function $s(\theta_f, \beta, \psi_f)$ [Eq. (31)] is approximately the ratio $\rho/\rho_{ns}$ between the amplitude $\rho$ of a spinning, precessing binary seen in band in a configuration and line of sight specified by $(\theta_f, \beta, \psi_f)$ and the amplitude $\rho_{ns}$ of a nonspinning binary of comparable masses.

064020-12
This trivial contour integral corresponds to identifying terms \( \propto u^n \) in \( z \) for different \( n \). The value of this contour integral depends discontinuously on the winding number \( n_{\text{wind}} \). Using the definitions of \( C, S \) to perform this integral, we find
\[
I = \begin{cases}
\frac{2}{3} \cos 2\psi_j \sin^2 \theta \\
\frac{2}{8} \sin \theta \sin 2\beta (\cos 2\phi_j \sin 2\theta \mp 2i \sin \theta \sin 2\phi_j) \\
-\frac{(1 + \cos \theta)^2}{8} [\cos 2\psi_j (1 + \cos^2 \theta) \mp 2i \cos \theta \sin 2\psi_j]
\end{cases}
\]

Finally, we estimate the fitting factor for all angles by dividing this closed-form expression by the closed-form expression for \( s \):
\[
F(\theta, \beta, \psi_j) \equiv |I(\theta, \beta, \psi_j)|/s(\theta, \beta, \psi_j). \quad (46b)
\]

This ratio varies strongly in all three parameters and is best summarized by the explicit expression above. Though complicated, some important physical lessons can be drawn. First and foremost, for nonprecessing signals the predicted fitting factor is \( F = 1 \). Second and most critically, while the predicted fitting factor has a local extremum with \( F \approx 1 \) in each of the three regions, the predicted fitting factor drops rapidly as we approach the surface defining them: at the surface defined by Eq. (15) and shown in Fig. 7. In other words, this expression suggests the worst possible matches will occur when the angular momentum at some point in the precession cycle is along one of the two null lines. As noted above, the low fitting factor in this region occurs because the signal consists of comparable amounts of power with two competing and incompatible secular phase trends. Finally, under special conditions such as \( \theta = 0 \) in R2 and R3, this expression predicts pathologically low matches \( P \approx 0 \). As we will discuss at greater length in a forthcoming publication, an empirically more successful approximation replaces the options in \( I \) by the maximum over the three options.

Though derived under the seemingly strong expression of a constant precession cone, we have verified this expression applies to a broad family of real BH-NS inspirals, by calculating the overlap between the gravitational radiation emitted from nonprecessing and precessing binaries and maximizing over the nonprecessing signal’s parameters. We will describe these Monte Carlo studies in more detail in a subsequent publication. In brief, these studies corroborate many earlier studies that examined how well nonprecessing signals recover precessing waveforms [20,31,37]. First, in special but not uncommon circumstances, fitting factors as low as 0.6 occur. Second, small fitting factors (i.e., large mismatches) can occur even with small amounts of spin-orbit misalignment, though they become more common as misalignment increases. For nearly aligned binaries, signals with the lowest match correspond to directions with low signal power. Contrary to previous claims, however, we identify some configurations with both a low fitting factor and a significant signal power along the line of sight.

This analytic study differs from all previous investigations in that we assume a nonprecessing signal model can always match any secular phase evolution, identify which precessing configurations lead to large modulations, and quantify the expected purely geometrical effect these modulations have on the fitting factor. As an example, in Fig. 11 we predict the distribution of fitting factors expected when a nonprecessing search is applied to a randomly oriented BH-NS binary. Despite the simplicity of our model, we recover quantitatively similar results to previous studies [31]. Unlike earlier studies, however, our expressions allow us both to identify precisely which binaries are least well fit and to understand precisely why.

FIG. 11 (color online). Distribution of fitting factors for single-spin BH-NS: Using only the analytic expressions provided in this paper, the predicted fraction \( P(>F) \) of fitting factors greater than \( F \) for a randomly oriented BH-NS binary with \( m_1 = 10M_\odot, m_2 = 1.4M_\odot \), with the dimensionless black hole spin \( \tilde{x}_1 \) randomly oriented and with magnitude uniformly distributed between 0 and 0.98. Compare to the solid line in the bottom right panel of Fig. 9 in Ref. [31], although there the neutron star also has a spin up to 0.3.
D. Validating our approximations with Monte Carlo

To demonstrate that our approximation works, we have compared randomly chosen BH-NS binaries with a standard nonprecessing template bank: Taylor F2 templates with physical parameters, a hexagonal template bank chosen for 97% minimal match, and a likely early advanced LIGO noise curve, the low-power zero-detune power spectral density [41] such that \( f_{\text{peak}} \approx 40 \text{ Hz} \).

For example, Fig. 12 shows the results for 30 000 BH-NS binaries \((10M_\odot + 1.4M_\odot)\) with random orientations for \( \kappa = \hat{L} \cdot \hat{S} > -1/2 \) and spin magnitudes \( a_1 \in [0, 1] \). The limit on \( \kappa \) removes some systems with transitional precession for clarity; in the next figure, we allow nearly the full range of \( \kappa \). The bottom panel shows the configurations of the worst-fit sources for two polarizations (\( J \) nearly aligned with the detector on the plane of the sky and 45° off the detector arms). Both cluster near the predictions of our model (dotted lines): our approximation correctly identifies the worst-fit locations. More generally, the top panel shows our estimate works (nearly) everywhere: it compares our fitting factor estimate \( F \) to the fitting factor \( F \) calculated by comparing that signal to the template bank. Despite known systematic differences between the signal and template model even for aligned systems, our match prediction works well almost everywhere. For comparison, the vertical dotted line at \(-0.03\) shows the typical mismatch expected from template bank discreteness.

In this comparison, we have artificially eliminated the small fraction of worst-performing configurations, corresponding to sources recovered with templates near the edge of the template bank where \( \eta = 1/4 \). The secular phasing due to the aligned component of the spin is best fit by templates with \( \eta \) biased to larger than its true value. Because of the finite parameter extent in \( \eta \) of physical Taylor F2 templates, the conventional signal model fails to capture even the secular effects of large aligned spins. An aligned but nonprecessing template bank would, however, be able to capture these signals. To faithfully reproduce signals with aligned spins using standard template banks, we must extend the bank into \( \eta > 1/4 \). This nearly captures the secular effect of aligned spins and is a reasonably good substitute for a true aligned-spin template bank.

Figure 13 shows the results of this extended-\( \eta \) bank, compared to a much larger set of BH-NS binaries. The top panel shows that our approximation continues to work well for generic sources, even given systematic differences between signal and template and the absence of spin. In particular, the bottom panel demonstrates that except for rare outliers, our approximation correctly identifies the worst-fit sources.

E. Beyond the constant precession cone

Though we emphasize the value of a (nearly) constant precession cone in approximating binary inspiral, the concepts and expressions we provide apply equally well to many
simply precessing binaries. As an example, in Fig. 14 we show the precession-induced phase evolution for two systems with slightly different $\beta$, such that they are near a transition between regions. One is in R1 and the other in R2. The nearness to the transition surface causes large oscillations around the secular increase in phase. Binaries whose opening angles $\beta(f)$ evolve across these boundaries and particularly across $\pi/2$ in band can undergo dramatic transitions in the properties of their observable waveform, accumulating only one helicity early on and another helicity later.

VI. CONCLUSIONS

In this paper we have explored two features of the gravitational-wave signal seen by ground-based detectors in a “constant precession cone” limit. We compare their amplitude to a similar face-on nonprecessing binary; we compare their waveform to the best-fitting nonprecessing signal. We find closed-form expressions for both quantities. Our expressions involve only geometrical parameters—the orientation of the precession cone relative to the line of sight—with no explicit reference to the (PN) phase model, detector noise curve, or binary parameters. In a subsequent paper we will use these factors to interpret the selection biases of optimal and nonprecessing searches for precessing binaries. This publication will provide explicit Monte Carlo simulation over all possible source parameters and sky locations and calculate overlaps using state-of-the-art signal models.

Nonprecessing searches for spinning binaries in...
the source and orientation of the detector (W). As a result, two independent detectors running two independent searches may identify two very different best-fitting (non-precessing) signals, due only to the detectors’ orientations. These biases in recovered parameters must be taken into careful account when constructing coincidence-based search algorithms. We will also address biases in recovered parameters in a future paper.
