(Dated: 16 March 2015)

We investigate the atomic and electronic structure of ultra-thin ZnO films (1 to 4 layers) on the (111) surfaces of Ag, Cu, Pd, Pt, Ni, and Rh by means of density-functional theory. The ZnO monolayer is found to adopt an α-structure on the metal substrates with coincidence structures in good agreement with experiment. Thicker ZnO layers change into a wurtzite structure. The films exhibit a strong corrugation, which can be smoothed by hydrogen (H) adsorption. An H over-layer with 50% coverage is formed at chemical potentials that range from low to ultra-high vacuum H₂ pressures. For the Ag substrate, both α- and wurtzite ZnO films are accessible in this pressure range, while for Cu, Pd, Pt, Rh, and Ni wurtzite films are favored. The surface structure and the density of states of these H passivated ZnO thin films agree well with those of the bulk ZnO(0001)-2x1-H surface.

ZnO polar surfaces are the formation energies and charge transition levels of common defects, the associated position of the films’ or surfaces’ Fermi level and the role of the image effect induced by the metal substrate. These will be investigated in future work.

We use DFT as implemented in the FHI-aims code together with the Perdew-Burke-Ernzerhof (PBE) functional and a Monkhorst-Pack k-grid of 15x15x15 k-points in the primitive unit-cell. We simulate surfaces as periodically repeated slabs. To compensate the artificial electrostatic field due to the asymmetric slab geometry we apply a dipole correction. ZnO films on metal substrates are initialized in an ideal α-BN structure. The geometry of the ZnO and the two metal layers closest to the interface is relaxed until the forces are below 0.05eV/Å per atom. Long range van-der-Waals effects were accounted for by the Thatchenko-Scheffler (TS)-scheme with parameters adapted to surface and polarization effects. The parameters are listed in the supplementary material (SI).

FIG. 1. (a) Structure of (8x8x2) ZnO on (9x9x4) Ag without H adsorption. (b) (8x8x2) ZnO on (9x9x4) Ag surface slab with 50% H coverage. (c) Zn0(0001)-2x1-H surface. Only parts of the unit-cells are shown.

In the context of hybrid inorganic/organic systems, ZnO is a common inorganic component for optoelectronic devices. However, the structure of the polar (0001) and (0001) surfaces, that is often used in these hybrid systems, is under heavy debate and (0001) surfaces, that is often used in these hybrid devices. ZnO is a common inorganic component for optoelectronic devices. In industrial catalytic processes, ZnO supported metal nanoparticles are frequently used to convert syngas. In both cases, metal supported ultra-thin oxide films have been proposed as model systems to understand the interface and its chemistry, because they facilitate quantitative interface studies. Another important application of ZnO lies in the field of heterogeneous catalysis. In industrial catalytic processes, ZnO supported metal nano-particles are frequently used to convert syngas. In both cases, metal supported ultra-thin oxide films have been proposed as model systems to understand the interface and its chemistry, because they facilitate quantitative interface studies. Another important application of ZnO lies in the field of heterogeneous catalysis. In industrial catalytic processes, ZnO supported metal nanoparticles are frequently used to convert syngas.

Thicker ZnO layers change into a wurtzite structure. The films exhibit a strong corrugation, which can be smoothed by hydrogen (H) adsorption. ZnO polar surfaces are the formation energies and charge transition levels of common defects, the associated position of the films’ or surfaces’ Fermi level and the role of the image effect induced by the metal substrate. These will be investigated in future work.

We use DFT as implemented in the FHI-aims code together with the Perdew-Burke-Ernzerhof (PBE) functional and a Monkhorst-Pack k-grid of 15x15x15 k-points in the primitive unit-cell. We simulate surfaces as periodically repeated slabs. To compensate the artificial electrostatic field due to the asymmetric slab geometry we apply a dipole correction. ZnO films on metal substrates are initialized in an ideal α-BN structure. The geometry of the ZnO and the two metal layers closest to the interface is relaxed until the forces are below 0.05eV/Å per atom. Long range van-der-Waals effects were accounted for by the Thatchenko-Scheffler (TS)-scheme with parameters adapted to surface and polarization effects. The parameters are listed in the supplementary material (SI).

For the smallest structures (i.e. ultra-thin ZnO on Cu) the PBE functional was tested against the higher level Heyd-Scuseria-Ernzerhof (HSE06) hybrid functional. The changes in relaxed ge-
ometries are small and the main difference in the density of states is the larger ZnO band gap (see SI\textsuperscript{38}). The starting point for our investigations are hypothetical free-standing ZnO films without a metal substrate. They adopt an \(\alpha\)-BN structure in analogy to graphene\textsuperscript{30–33}. To obtain a stable combination of metal and ZnO monolayer we have to address the lattice mismatch between the two constituents. Too much strain will force the film out of its preferred planar structure towards a wurtzite-like structure\textsuperscript{34}. According to our calculations (see Fig. 2\textsuperscript{c}) the switch from planar to wurtzite occurs at a ZnO in-plane lattice parameter of 3 Å (\(~9\%\) strain). The strain in the films can be minimized by tuning the coincidence to match the in-plane lattice parameter of the ZnO ultra-thin films on metals with the lattice parameter of the free-standing mono-layer ZnO. We confirmed this observation by considering the formation energy \(\Delta H\) of the combined system (ZnO mono-layer on metal) as a function of the number of unit-cells \(m\) along the in-plane lattice vectors of the metal:
\[
\Delta H = (E_{Tot} - m^2 E_M - (m - 1)^2 E_{ZnO})/A,
\]
with the total energy of the coincidence slab \(E_{Tot}\), the energy of the 1x1 metal surface \(E_M\), the energy of free-standing 1x1 ZnO mono-layer \(E_{ZnO}\) and \(A\) the surface area of the structure. For \(m \times m\) metal unit cells with a fixed lattice parameter \(a_M\) this results in \((m - 1) \times (m - 1)\) unit-cells of ZnO with a ZnO lattice parameter of \(a_{ZnO} = \frac{m - 1}{m} \sqrt{2}\). The results are shown in Tab. I. The agreement with experimental values for sub-monolayer ZnO islands is good (Ag\textsuperscript{35,36}, Pd\textsuperscript{37}, Pt\textsuperscript{38}, Au\textsuperscript{39}, Cu (brass\textsuperscript{40}, Ru (0001)\textsuperscript{41}).

\(\Delta \Phi\) is the work function change between the bare metal surface and the ZnO mono-layer on the metal substrate. The free-standing monolayer would not exhibit any corrugation within the range of residual strains observed for ZnO on the metal substrates (see Fig. 2\textsuperscript{c}). We attribute the larger corrugation of ZnO on Cu, Rh, Pd and Pt to chemical effects such as a larger affinity for oxygen and thus a prevalence for oxide formation and the different distances between surface metal atoms and ZnO due to the varying size of the coincidence structures. With growing number of ZnO layers on the metal substrates the corrugation of the ZnO ultra-thin films increases. Strain in the ZnO films (Cu, Ni, Pd) facilitates the formation of a bulk-like wurtzite structure. We will restrict our investigations to the O-terminated multi-layer ZnO films on the metal substrates and investigate their stability with respect to a residual H atmosphere. A more detailed analysis of both terminations including the influence of OH and other reconstruction is deferred to future work.

The phase diagrams for different coverages of H on ZnO ultra-thin films on different metals as function of the number of ZnO layers are now analyzed by \textit{ab initio}
FIG. 3. (a) Surface free energy $\gamma$ per (1x1) Ag surface unit-cell area as function of the change in chemical potential $\Delta \mu$ (see eq. 2) for 2 Layers (8x8) ZnO on (9x9x4) Ag with different coverages of H. The partial pressure, as calculated from thermodynamical tables, of H$_2$ at 400K is plotted in the top axis. The red area indicates the transition region between the ultra-thin film without H (dark gray) and the 2x1-H with 50% H coverage (light gray). (b) The three different regimes corresponding to the dark gray, colored and light gray areas in (a) for different metals and different numbers of ZnO layers (L).

atomistic thermodynamics. We consider the surface free energy $\gamma$:

$$\gamma(T, p_H) = \frac{1}{A}[E^{\text{tot}} + F^{\text{vib}} - T S^{\text{conf}} + pV - N_M E^{\text{bulk}}_M - N_{\text{ZnO}} E^{\text{bulk}}_{\text{ZnO}} - N_H \Delta \mu_H(T, p_H)]$$

(2)

as a function of the change of the H chemical potential, $\Delta \mu = \mu_H - E_{H_2}/2$. $E^{\text{tot}}$ is the total energy of the slab-calculation, $N_M$, $N_{\text{ZnO}}$, $N_H$ the number of the respective species and $E^{\text{bulk}}_M$, $E^{\text{bulk}}_{\text{ZnO}}$, $E_{H_2}$ the reference energies of their bulk or molecular forms, obtained with the PBE+vdw xc-functional (see SI). $F^{\text{vib}}$ is the vibrational free energy, $S^{\text{conf}}$ the configurational entropy, $p$ the total pressure and $V$ the total volume. The impact of these three contributions on the surface phase diagrams can be found in the literature and in detail for ZnO on metal substrates in the SI. The $pV$-term can be safely neglected. The effect on the 2x1-H reconstruction is less pronounced due to the steep inclination ($N_H$/surface sites) of its stability line in the phase diagram (Fig. 4a). In Fig. 4b and for the further discussion vDW-effects, $S^{\text{conf}}$ and $F^{\text{vib}}$ are taken into account.

The chemical potential is translated into partial pressures for a given, exemplary temperature (400K) with the help of the ideal gas law and thermodynamic tables. Our calculations show that the bulk terminated ZnO surface is only stable for low H$_2$ partial pressures. At elevated chemical potentials of H$_2$ the 2x1-H structure becomes the most stable surface (see Fig. 1b and Fig. 3). Disordered H distributions, H at the interface and H adsorbed at the Zn-sites are higher in energy (see SI). With increasing H termination, the films become more and more wurtzite-like and the surface adopts the 2x1-H structure. For all calculated systems the partial pressure region for the transition from the clean ($\alpha$-BN) film to the 2x1-H reconstruction is shown in Fig. 3b. Below low the colored bars (dark gray regions, lower pressures), the graphite-like films are stable, above (light gray region, higher pressures) 2x1-H is stabilized. In the region marked by the bars H-coverages larger than 0% and smaller than 50% are stable. H coverages corresponding to one H per unit cell (determined by the coincidence structure) dominate this transition regime. Our results show that for Ag the clean surface as well as the 2x1-H reconstruction could be realized experimentally for layer numbers greater than 2 for 400K. Thus the H$_2$ partial pressure can be used to select one of the two phases. For Cu and Ni the structure without H and the intermediate H-coverages are reachable only at elevated temperatures. For Pd and Rh only the 2x1-H reconstruction is within experimentally accessible pressure ranges. For increased H pressures, the difference in formation energies between systems with different numbers of ZnO layers is significantly reduced (see SI). Under experimental conditions, some of these structures could be kinetically stabilized and further growth be hindered. The formation of the 2x1-H reconstruction, though thermodynamically most stable, could be blocked by an energy barrier for the dissociation of H$_2$ at the surface.

Finally we address the electronic structure. The comparison of the density of states for the 2x1-H reconstructed ZnO (0001) surface and the ZnO films on the metals in Fig. 4 shows that systems with 4 and more layers already resemble the 2x1-H reconstructed ZnO (0001) surface very well. The films without H retain a unique character. The electronic structure differs from the ZnO (0001)-2x1-H surface and the geometry combines aspects of wurtzite and $\alpha$-BN.

In summary we have shown stable coincidence structures for bulk-terminated ZnO thin films on Ag, Cu, Pd, Ni, Pt and Rh. The mono-layers exhibit a graphene-like $\alpha$-BN structure with a pronounced corrugation depending on
the lattice mismatch with the substrate. With increasing number of ZnO layers the \(\alpha\)-BN structure destabilizes. For increased \(H_2\) partial pressures the atomic and electronic structure resembles that of bulk terminated ZnO (000\(\overline{1}\))-2x1-H (see Fig. 1c), whereas at low \(H_2\) partial pressures \(H\)-free graphitic ultra-thin films are stable. The choice of metal and the \(H\) partial pressure are therefore two additional degrees of freedom to select between ultra-thin ZnO films, that differ from bulk ZnO, and films that resemble wurtzite ZnO and could serve as important models for the study of the ZnO (000\(\overline{1}\))-2x1-H surface.

The authors thank Prof. Dr. Matthias Scheffler, Dr. Shamil Shaikhutdinov and Dr. Takashi Kumagai for fruitful discussion in the process of this work. This work was supported by the Deutsche Forschungsgemeinschaft DFG through the collaborative research project 951 "HIOS", by the Austrian Science Fund FWF through the Collaborative Research Project 1078, and by the Academy of Finland through its Centers of Excellence Program (#251748).

FIG. 4. (a) Comparison of projected DOS of 4 Layers (8x8) ZnO on (9x9x4) Ag without H and (b) with 50% H coverage with the DOS of a ZnO 2x1-H surface slab. The projected DOS of the ZnO 2x1-H surface is shifted by -1eV in (a) and (b) with respect to their Fermi level.
